UNIQUE

Full-cycle endometrial support, with no late-cycle progestin increase.

The unique TRI-NORINYL phasing achieves BTB control equivalent to a 1/35 formulation, but with 29% less progestin per cycle. This is, in fact, the greatest progestin reduction of any norethindrone-based multiphasic. TRI-NORINYL lowers progestin where requirements for endometrial support are reduced—with no greater reported BTB than a 1/35 formulation.*

SUPPLIED IN THE EXCLUSIVE SYNTEX WALLETTE™ PILL DISPENSER

Preferred by patients 3 to 1 over other available packages for convenience, discreetness and compliance.**

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

*1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. Data available from Syntex Laboratories, Inc.

**Based on a nationwide, independently conducted survey of prospective oral contraceptive patients. Data available from Syntex Laboratories, Inc.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism, CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OC. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk.
B–Use associated with high risk.
C–Use associated with moderate risk.
D–Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests *Chlamydia trachomatis* infection, the leading cause of nongonococcal P.I.D., is enhanced by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

MILES
Miles Pharmaceuticals

Mycelex® Twin Pack
(clotrimazole)

One-day therapy
Mycelex®-G 500mg
(clotrimazole) Vaginal Tablet

Seven-day therapy
Mycelex® 1%
(clotrimazole)
Cream

Indications
MYCELEX®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one-day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended.
MYCELEX® CREAM is indicated for the topical treatment of dermal infections due to *Candida albicans*.

Contraindications
MYCELEX-G 500 mg Vaginal Tablets and MYCELEX CREAM are contraindicated in women who have shown hypersensitivity to any of their components.

Warnings
MYCELEX-G 500 mg Vaginal Tablets: none. MYCELEX CREAM is not for ophthalmic use.

Precautions
MYCELEX-G 500 mg Vaginal Tablets: If there is a lack of response to the Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.
MYCELEX CREAM: If irritation or sensitivity develops with the use of Mycelex Cream, treatment should be discontinued and appropriate therapy instituted.

Carcinogenesis
MYCELEX-G 500 mg Vaginal Tablets: No long-term studies in animals have been performed to evaluate the carcinogenic potential of 500 mg Vaginal Tablets intravaginally. A long-term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.

Usage in Pregnancy: Pregnancy Category B:
MYCELEX-G 500 mg Vaginal Tablets: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.
In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy.
Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.
MYCELEX CREAM: In the first trimester of pregnancy, Mycelex Cream should be used only when considered essential to the welfare of the patient.

Adverse Reactions
MYCELEX-G 500 mg Vaginal Tablets: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.
MYCELEX CREAM: The following reactions have been reported in connection with the use of this cream: erythema, stinging, blistering, peeling, edema, pruritus, urticaria, and general irritation of the skin.

The simplest way to

There are still many who perform a CBC or hematocrit as soon as anemia is suspected, even though it is in fact the Hb value that defines anemia.

There is a simpler way.

Determine the Hb level directly. If it lies below the reference standard, it is reasonable to suspect anemia. A detailed patient history will then disclose whether it is caused by a deficiency in iron or loss of blood.

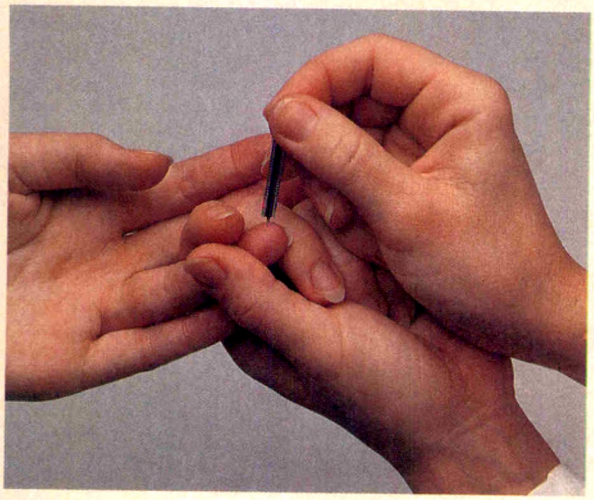
But...

The Hb level varies from person to person. It thus makes sense to monitor each individual patient's Hb level routinely to identify early signs of anemia.

For this you would require a test procedure that could be performed in-office with minimal risk of functional and human error.

This is where the HemoCue Hb test comes in.

The HemoCue system is designed to eliminate possible sources of error. It is so simple to handle that anyone can perform accurate Hb determinations in 60 seconds or less.



Going the long way around through CBC, or via hematocrit, you can get there quicker and safer with HemoCue. And have the test result before the patient leaves your office!

For more information on this new, economical test, call 800-323-1674 (CA 714-859-7779).

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR.)*

PREMARIN® Brand of conjugated estrogens tablets, USP

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens tablets, USP) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens.

INDICATIONS AND USAGE: Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown th there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer a women for postpartum breast engorgement. Users of oral contraceptives have an increased ri of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarctio Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported oral contraceptive users. An increased risk of postsurgery thromboembolic complications h also been reported in users of oral contraceptives. If feasible, estrogen should be discontinue at least 4 weeks before surgery of the type associated with an increased risk of thromboer bolism, or during periods of prolonged immobilization. Estrogens should not be used in perso with active thrombophlebitis, thromboembolic disorders, or in persons with a history of su disorders in association with estrogen use. They should be used with caution in patients wi cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per da comparable to those used to treat cancer of the prostate and breast have been shown increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebiti When doses of this size are used, any of the thromboembolic and thrombotic adverse effec should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pa and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has bee reported in women taking estrogen-containing oral contraceptives. Increased blood pressu may occur with use of estrogens in the menopause and blood pressure should be monitore with estrogen use. A worsening of glucose tolerance has been observed in patients c estrogen-containing oral contraceptives. For this reason, diabetic patients should be careful observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bor metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should b taken prior to the initiation of any estrogen therapy with special reference to blood pressur breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a gener rule, estrogen should not be prescribed for longer than one year without another physic examination being performed. Conditions influenced by fluid retention, such as asthma, ep lepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patien may develop manifestations of excessive estrogenic stimulation, such as abnormal or exce sive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estroge therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Or contraceptives appear to be associated with an increased incidence of mental depressio Patients with a history of depression should be carefully observed. Pre-existing uterin leiomyomata may increase in size during estrogen use. The pathologist should be advised estrogen therapy when relevant specimens are submitted. If jaundice develops in any patie receiving estrogen, the medication should be discontinued while the cause is investigate Estrogens should be used with care in patients with impaired liver function, renal insufficienc metabolic bone diseases associated with hypercalcemia, or in young patients in whom bon growth is not yet complete. If concomitant progestin therapy is used, potential risks may includ adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increase norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroi hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptak is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done onl when clearly necessary since man drugs are excreted in human milk.

Long-term, continuous administra tion of natural and synthetic estro gens in certain animal species in creases the frequency of carcinoma of the breast, cervix, vagina, and live However, in a recent, large case-con trolled study of postmenopausa women there was no increase in risk of breast cancer with use of conju gated estrogens.

ADVERSE REACTIONS: The fol lowing have been reported with es trogenic therapy, including oral con traceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; pre menstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterin fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secre tion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persis when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short-term use only.* For treatmen of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associate with the menopause (0.3 mg to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should b discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration.

Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

Female castration—1.25 mg daily cyclically. Adjust upward or downward according to re sponse of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

What's the difference between
OVCON®
(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets
35
...and Tri-Norinyl®
Ortho-Novum™ 7/7/7,&
Ortho-Novum™ 1/35?

they contain 78% to 150% more norethindrone per cycle!

Amounts of norethindrone per cycle

the OC with the lowest norethindrone dose

Ovcon®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Mead Johnson

OVCON®-50

(norethindrone [1 mg] and ethinyl estradiol [0.05 mg]) tablets

OVCON®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg. or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50–80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15–34, 5/100,000; ages 35–44, 33/100,000; ages 45–49, 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications and there is no evidence from well-controlled studies that progestins are effective for these uses. Increases in chromosomal aberrations have been reported in women who become pregnant soon after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should be discussed in light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months. Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleeding should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies have reported an increased risk of surgically confirmed gallbladder disease appearing after one year of oral contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. Increased serum levels of triglycerides and total phospholipids have been observed in oral contraceptive users. The clinical significance of this observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure has been reported in women receiving oral contraceptives. The prevalence of hypertension in oral contraceptive users may be no higher than nonusers in the first year of oral contraceptive use but increases with longer exposure and in the fifth year of use is two and one-half to three times the reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of oral contraceptives and investigation of the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of oral contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than 1 year without another physical examination being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG, free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. 11) The active yellow tablets and the inert green tablets in Ovcon-50 (21 and 28 day regimens) and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (other reactions, as a general rule, are seen much less frequently or only occasionally); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

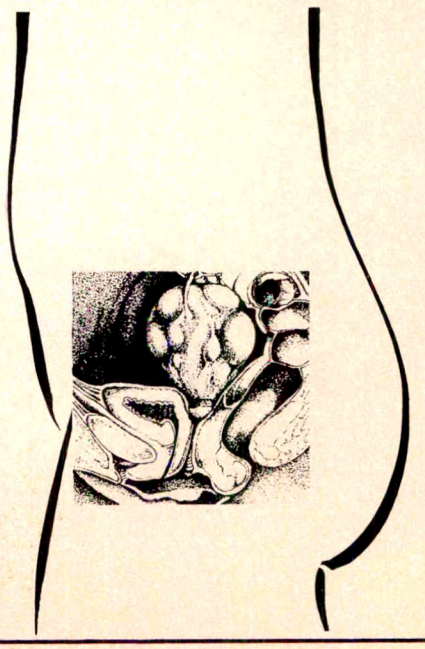
THE FIRST INTERNATIONAL CONFERENCE ON



VAGINAL SURGERY:

Today's and Tomorrow's Techniques and Choices

Friday and Saturday,
March 6-7, 1987
St. Louis, Missouri
Doubletree Hotel and Conference Center

Physicians of renown will report on their personal experiences with various vaginal surgical techniques and their reasons for selecting and performing vaginal surgery.

This unique—not to be missed—conference will focus on far-reaching practical implications of vaginal surgery for the clinician to augment his/her surgical skills in a changing and demanding marketplace.

Presented by St. John's Mercy Medical Center, St. Louis, Missouri

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manu-

script and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
—Title of article
—Full name(s) and affiliations of author(s)
—Author to whom correspondence is to be sent
—Reprint request line or line stating reprints not available
—Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

TRI-LEVLEN

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

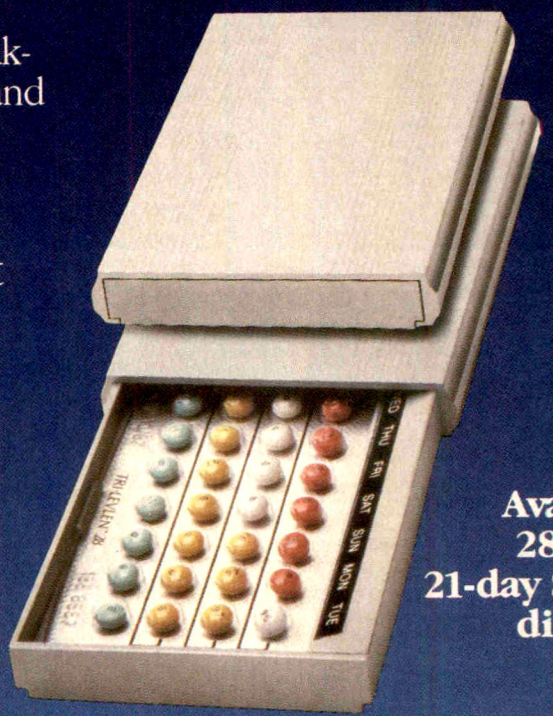
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These da represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

A formulation with the lowest total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Low incidence of breakthrough bleeding



A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

Minimal impact on the following metabolic and hemodynamic parameters*

Lipids;[2,3] carbohydrate metabolism[2,3] and blood pressure[1] were not significantly affected in certain specific studies.

A formulation with the confidence of 170 million cycles of experience worldwide

Available in 28-day and 21-day Slidecase™ dispensers

BERLEX™ **Dedicated to innovation in OB/GYN medicine**

TRI·LEVLEN™ 28
TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

CLINICAL SECTION

Clinical Opinion

Screening for postmenopausal osteoporosis

Margaret R. Davis, M.D.

Washington, D. C.

Postmenopausal osteoporosis is an area of increasing concern to the gynecologist. Fractures will develop in approximately 15% to 25% of women in their later years and preventive therapy is best aimed specifically at this group. Predicting who will be the ones to sustain fracture is a difficult and imprecise clinical task. The clinical, laboratory, and radiologic methods available for this purpose are reviewed. A rational approach to this problem in today's setting is outlined. (AM J OBSTET GYNECOL 1987;156:1-5.)

Key words: Osteoporosis, bone mineral content, photon absorptiometry, computed tomography

The clinical diagnosis of osteoporosis is made when an atraumatic fracture associated with qualitative or quantitative evidence of reduced bone mass is documented. Recently postmenopausal osteoporosis has become a burgeoning area of interest in terms of medical, social, and economic costs; it is also a problem that is appropriately coming under the purview of the gynecologist. Prevention of fracture is the primary goal of intervention. To routinely identify women at particular risk, one should have reasonable and cost-effective screening criteria that demonstrate the ability to predict the likelihood of future fracture.

This article will review for the clinician the clinical, laboratory and radiologic methods used in screening patients for the development of postmenopausal osteoporosis. A conclusion will be drawn regarding a rational approach that could be used to determine who might benefit from specific preventive measures.

History

The correlation of osteoporosis with the following factors is well documented: white and Oriental race, slender build and short stature, and the onset of early menopause (natural or surgical). A history of nontraumatic fractures in other female family members is significant.

The relationship of osteoporosis to dietary factors is less firmly established, but some dietary factors may be of importance by virtue of their effect on calcium metabolism and body weight. Poor calcium intake has been identified in a significantly greater percentage of patients with osteoporosis than in the general population. Diets high in caffeine, alcohol, phosphorus, animal protein, and some acidifying foods decrease calcium absorption or promote excretion.

Other life-style habits should be investigated. Cigarette smoking has been linked to earlier menopause. Bone loss is accelerated with immobilization and prolonged bed rest; thus sedentary living is an additional risk factor.

Table I lists some causes of secondary osteoporosis. Careful questioning for a history of those conditions or symptoms suggesting them, along with a drug history, is mandatory.

Even patients with established osteoporosis may offer no symptoms. Severe, local back pain may develop during routine activity, but usually subsides within several months. Persistent pain can occur from altered spinal mechanics, but many compression fractures cause no pain at all. The patient may report body shortening or a "dowager's hump." Severe kyphosis can promote pulmonary dysfunction, abdominal discomfort, early satiety, bloating, and constipation.

Progressive loss of alveolar bone leading to tooth loss

From the Department of Obstetrics and Gynecology, George Washington University.

Table I. Causes of secondary osteoporosis

Hyperthyroidism
Hyperparathyroidism
Hypercortisolism
Hypogonadism
Renal dysfunction
Malabsorption disorders
Connective tissue disorders (such as osteogenesis imperfecta)
Neoplastic disease (such as multiple myeloma)
Drug use
Heparin
Corticosteroids
Anticonvulsants
Aluminum-containing antacids
Methotrexate

may be a manifestation of osteoporosis. An early need for dentures with frequent refittings and a history of periodontal disease should alert the clinician.

Physical examination

The only physical signs may be loss of height or the development of kyphosis, or both, with loss of lumbar lordosis. Signs of other diseases should be sought.

Simplified anthropometric measurements should be recorded, including accurate weight, standing height, and arm span. At bone maturity (approximately 30 years of age), arm span should equal head-to-heel height. Skin-fold measurements can be made with a skin-fold caliper at the subscapular, suprailiac, triceps, and calf sites; by using reference tables, an estimation of the percent of body fat, which does correlate with the development of osteoporosis, is derived. It is of interest that although osteoporosis and osteoarthritis are both common in the older age groups, they are rarely seen together; indeed, the anthropometric profile for each is quite separate, with differences in skin-fold thickness constituting the most important distinction.

Laboratory methods

No one laboratory method has been found to screen reliably for postmenopausal osteoporosis. In the uncomplicated case, complete blood count, sedimentation rate, serum protein electrophoresis, calcium, phosphorus, alkaline phosphatase and urinalysis values are all normal. These tests and others, however, are useful in identifying causes of secondary osteoporosis. For example, a low serum calcium level, a serum phosphorus level <3 mg/dl, or an elevated alkaline phosphatase level should prompt one to pursue the diagnosis of osteomalacia.

Calcitonin levels and reserve do not correlate with bone density.[1] Hydroxyproline excretion is similar in osteoporotic and nonosteoporotic groups of women. Several more specialized tests have been studied. Serum bone Gla protein is a specific marker for bone turnover but may be high, normal, or low in osteoporotic patients, reflecting the heterogeneity of histologic findings.[2] One study examined alkaline phosphatase isozymes and suggested that elevated bone isozyme levels in the perimenopausal period predisposed to the development of osteoporosis as reflected in higher fracture rates.[3]

Hormonal parameters have also been investigated. Most studies show no major differences in cortisol, androstenedione, estradiol, and estrone levels in osteoporotic and normal women. Johnston et al.[4] found that menopausal women who are "rapid bone losers" have very low circulating progesterone levels (<0.5 ng/ml), whereas "slow bone losers" have significantly higher levels. However, this is not a specific or highly discriminating test. Recently, the potential usefulness of a short-term gonadotropin-releasing hormone antagonist test has been investigated in primates. Its aim would be to prospectively predict an individual's risk of osteoporosis by assessing her vulnerability to negative calcium balance with estrogen deficiency.[5]

Two tests are commonly used in the early identification of clinical osteoporosis. An elevated fasting urinary calcium/creatinine ratio (>0.16) and an elevated fasting urinary hydroxyproline/creatinine ratio (>0.012) suggest rapid bone turnover with excess osteoclast activity. Again these are nonspecific parameters and there is substantial overlap in results from normal and osteoporotic groups of women.

Histomorphometry

Histomorphometry, usually performed on a bone biopsy specimen from the iliac crest, remains the most definitive invasive study for osteoporosis. Osteomalacia and certain forms of secondary osteoporosis can be excluded. Although the biopsy evaluates only one area of bone, it is a quantitative measurement and provides a reliable diagnostic indication of skeletal disease. The concept of histologic heterogeneity of postmenopausal osteoporosis has recently been developed on the basis of analyses of iliac crest bone biopsies. Although there is little morbidity in the technique, specialized equipment and expert analysis are required, and patient acceptance may be low. It can be reserved for a selected group of patients.

Radiologic methods

Standard radiographs. Before reduction of bone mass can be detected on standard films, 20% to 40% of bone mineral must be lost. Characteristic abnormalities on lateral spinal films include radiolucency of the vertebral spongy bone compared with the subchondral plates. Concave defects in the upper and lower surfaces of involved vertebra are noted, with

prominence of the vertical trabecular pattern. One or more vertebral crush fractures may be seen. X-ray evidence of osteoarthritis is usually lacking. In the peripheral skeleton there is diffuse demineralization with cortical thinning of the long bones. A standard panoramic dental radiograph may indicate severe residual alveolar ridge reduction. These methods are relatively crude and insensitive. If used as screening measures, a high degree of bone loss will already have occurred before preventive measures can be instituted.

Radiogrammetry. This is a standard x-ray technique that measures the thickness of the cortex of metacarpal or other tubular bones. It requires the ability to take reproducible bone radiographs and make fine-caliber measurements. The outer diameter of the bone is measured along with the marrow cavity diameter; subtraction gives the combined cortical thickness. Compared with those of a large, normal population, these measurements are usually quite precise, and this can be a good technique for cross-sectional and longitudinal studies. Because absolute bone mineral content and intracortical porosity are not measured, however, this method only provides information on relative changes in bone volume. Moreover, it is only applicable to the appendicular skeleton. Nonetheless, decreased cortical thickness is a measure of decreased bone mass, and spine and hip fractures are uncommon among women having a normal cortical thickness. The incidence of such fractures increases with decreasing cortical diameter.

Microradioscopy of the hand bone involves the aforementioned method with the use of fine-grain industrial film and increasing exposure time. With this procedure, cortical thickness and intracortical porosity can be measured separately, allowing assessment of endosteal and intracortical resorption. The linear endosteal resorption rate can be determined over a period of time; inasmuch as estrogen loss promotes bone resorption at that site, this simple procedure may be useful for detection of early developing osteopenia in perimenopausal women.[6]

Photodensitometry. Photodensitometry uses the bone mineral image on standard x-ray film as an indicator of photon absorption by bone and thus an indirect measurement of bone mineral content. The degree of whitening of the film is measured by a photodensitometer and compared with a simultaneous exposure of a calibrated bone mineral analogue. Bones with little overlying soft tissue, such as the radius, are best measured. Some researchers have found good correlation between radial bone mineral mass measured by this method and the partial body calcium mass measured by in vivo neutron activation, suggesting that changes in the proximal radius parallel those in the central skeleton. However, the technique does require expertise and is somewhat time-consuming. Precision (reproducibility) and accuracy is relatively poor.[6,7]

Singh index. The change in the trabecular pattern of the proximal femur is the basis of the Singh index. When bone mass is diminished, the first trabeculae to disappear are those subject to minor functional stresses. The disappearance of various groups of trabeculae seems to occur in a precise order, allowing the recognition of seven degrees of progressive osteopenia. A standard x-ray of the pelvis is taken, with the lower limbs slightly internally rotated to better view the proximal femur. Quantitative values for bone mineral content have been obtained by densitometric methods that correlate with each of Singh's categories. Although the Singh technique is easy to perform and interpret, the accuracy is poor, and prospective studies have concluded that the Singh index is of little prognostic value.[8]

Compton scattering. This is a largely experimental approach that measures trabecular bone density by using Compton scattered radiation. The extent of scattered radiation depends on the electron density (thus total density of bone plus marrow) of the scattering medium. The precision and accuracy of density determinations is about 3%.[9]

Single- and dual-photon densitometry. Single-photon absorptiometry is now probably the most widely used technique for estimation of bone mass. A highly collimated beam of monoenergetic radiation is passed across a limb, and the transmitted radiation is monitored with a scintillation detector. To ensure even soft tissue coverage, the limb is encased in a water bath or other tissue-equivalent medium. The amount of mineral in the bone is proportional to the change in intensity of the beam, and bone mass is calculated by comparing it with known standards. The most widely studied site is the radius. In an attempt to correlate more closely with the axial skeleton, a "5 mm site" has been established for measurements near the distal radius, which may be composed of more than 50% trabecular bone.[10] Precision (reproducibility) is good, 2% to 5% in the clinical setting. The principal determinant is repositioning at the same site on repeated scans. Because the distal radius is irregular in shape, whatever advantage is gained by measuring there, where more active trabecular bone is present, may be lost in reduced precision.

From repeated measurements of this kind, data have been computed, averaged, and printed out on a "fracture index chart." Serial measurements are plotted on the chart every 6 to 12 months, and the fracture risk is predicted. Specifically, bone density (mineral content/bone width) of 325 mg/cm^2 was found to be a "fracture threshold"; it is the distal radius density value >95% of all values from fracture patients.[11] Unfortunately, overlap among groups is significant, in the range of

Table II. Radiation exposure of various techniques

Technique	*Local exposure (mrem)*
Radiogrammetry	≤100
Photodensitometry	≤100
Compton scattering	300 - 500
Photon absorptiometry	
Single-energy	2 - 5
Dual-energy	5 - 15
Computerized tomography	
Single-energy	200 - 250
Dual-energy	250 - 400
Neutron-activation analysis	300 - 5000

15% to 20%. As might be expected, this technique does not consistently reflect changes occurring in other parts of the skeleton and other types of bone.

Attempts to apply single-photon absorptiometry to areas of trabecular bone have been only partially successful. Major problems include soft tissue interference and increased precision errors in measuring at many sites. The os calcis (calcaneus or "heel bone"), which is more readily accessible, has been measured by means of rectilinear scanning methods, necessary because of its irregular shape. The extent of os calcis demineralization seems to correlate better with the degree of spinal osteopenia and shows a consistent relationship to fracture prevalence. It has been postulated by some that this measurement is the best predictor of nonspine and spine fracture risk, short of actual density determinations of the site in question.[12]

Dual-photon absorptiometry makes measurements at two distinct energies, thereby eliminating the need to have constant thickness of soft tissue around the bone. Direct measurements of the femoral neck and spine are feasible. Like the single-photon method, however, it cannot discriminate between cortical and trabecular bone at these sites. The long-term precision is approximately 2% to 3%, and its greatest reliability is in following changes in skeletal bone mineral content over a period of time. Good discrimination is seen between subjects with fractures and control subjects; those with compression fractures average approximately 2 SD below control values but only 1 SD below normal in radius bone density. It has also been demonstrated that sequential changes occur much more rapidly in the lumbar spine than in the appendicular skeleton, one of the reasons that single-photon absorptiometry methods are relatively poor in predicting fracture risk.

Single- and dual-energy computerized tomography. The usefulness of computerized tomography for measurement of bone mineral is its ability to obtain a quantitative image in either the axial or the appendicular skeleton and separately measure trabecular or cortical bone. Recently, sophisticated modifications in standard computerized tomographic scanners, with the use of special software and calibration techniques, have specifically allowed determination of vertebral cancellous bone mineral content with a precision of 2% to 3%.[13] Excellent correlation has been found between vertebral trabecular mineral determined by computerized tomography and iliac crest trabecular bone volume determined by histomorphometry.[14] Individual patients with rapid bone loss can be identified in 12 to 24 months. The relationship of vertebral mineral content by computerized tomography to fracture risk is similar to other bone mass measurement techniques; that is, there is a threshold value above which fractures are unlikely and below which they may occur. It has been found that compression fractures or vertebral wedging was generally absent in patients with vertebral mineral values >110 mg/cm^3, whereas almost all patients with values <65 mg/cm^3 suffered fractures.[15]

Neutron activation. Neutron activation analysis is considered the "gold standard" for calculating body calcium content. By neutron irradiation the calcium 48 of the body is converted to calcium 49, and the subsequent decay back to calcium 48 is measured with a counter. Because calcium is a constant fraction of bone mineral, it can be interpreted as an indicator of skeletal mass. Any extraosseous calcification will detract from the method's validity. Both total body and local calcium content can be measured; however, this method that is limited to the spine, for instance, involves higher radiation doses with a precision of 3% to 5%. As with the other techniques, overlap is seen in results obtained from osteoporotic and normal populations.[16]

Comment

No single measurement, even the most perfect, will accurately discriminate between patients who will and will not have fractures. Other variables, including wide biologic variation, time, and stress, all factor in with bone density in determining the potential for osteoporosis. In considering the above methods for clinical practice, the information that can be derived from them and their limitations should be kept in mind. Options range from fairly gross measurements of integral (cortical plus trabecular) bone in peripheral sites to precise quantitation of trabecular bone in vertebral sites. Common sense would lead one to believe that the best techniques would be the ones that measure the actual areas of greatest clinical concern—the spine and the hip. Dual-photon absorptiometry and computerized tomograpic scanning are the two methods that meet these criteria for clinical utilization. They have low errors of precision and accuracy and have been shown repeatedly to be useful for diagnosis and for monitoring of changes.

In addition, other considerations are important. All

of the noninvasive methods for determining bone mass involve a radiation dose (see Table II). Practicality would dictate that only the standard radiographic methods and single-photon densitometry are easily adapted to routine screening in a private office; these are the least discriminating tests to use in predicting risk. Cost, of course, will also dictate what is practiced. Computerized tomographic scanners cost $750,000 to $1 million, with testing charges of $300 to $500. The cost of a dual-photon bone scanner ranges from $35,000 to $40,000, with scanning costing $125 to $200. A single-photon densitometer is priced less than $20,000. Third-party payments of these costs are variable at best. The Blue Cross–Blue Shield insurance plan presently recommends that both single- and dual-photon absorptiometry be considered "experimental/investigational" and therefore not covered. Local plans may or may not opt for this. In Florida, insurance covers single-photon absorptiometry if the diagnosis is osteoporosis but not if it is used as a screening tool. In New York, single-photon absorptiometry is reimbursable whereas the dual method is not.

The long-term efficacy of therapeutic methods is not definitely known, but it is estimated that prophylactic hormone replacement in postmenopausal women could reduce the hip fractures rate by 40% to 60%. The current diagnostic related group (DRG) allowance for treatment of hip fracture is approximately $9000. Yearly bone scans and endometrial biopsies for a woman from 50 to 80 years of age may approach that figure, but of course the number of women screened and treated will far exceed the number who sustain fracture.

With technology as it presently exists, most clinicians for most patients will probably continue to rely heavily on clinical data alone in evaluating for postmenopausal osteoporosis. Patients considered on a clinical basis to be at especially high risk may warrant referral for dual-photon absorptiometry or computerized tomographic scanning. These should be done annually at least through the 8 to 10 years immediately after menopause, when maximal bone loss is occurring. Third-party coverage should become standard. It is not to be presumed that hormone replacement therapy is warranted only in those who undergo scanning and are found to have decreased bone mineral content.

Breech delivery: Why the dilemma?

Stephen A. Myers, D.O., and Norbert Gleicher, M.D.
Chicago, Illinois

A critical review of selected studies of breech delivery is presented with special attention to the statistical analysis of outcome for low birth weight and term breech delivery. Analysis of the data fails to support the routine use of cesarean birth for all cases of breech delivery except for those with hyperextension of the head. The implication of these findings is discussed. (Am J Obstet Gynecol 1986;155:6-10.)

Key words: Breech delivery, cesarean section

Cesarean delivery rates continue to increase in spite of National Institutes of Health consensus report recommendations to the contrary. The abdominal route of delivery is often chosen even when clear, convincing data fail to demonstrate any advantage over the vaginal route, with repeat cesarean sections representing the most significant example. Because breech delivery accounts for only 10% to 15% of all cesarean sections (3% of all deliveries) and because many authors advocate routine cesarean section for breech delivery, not much attention has been focused on this cesarean delivery indication. It is the purpose of this review to critically analyze the obstetric literature in order to answer the question of whether cesarean section for breech presentation results in better obstetric outcome when compared with vaginal delivery. An all-encompassing review of the breech literature is neither relevant to the above question nor within the scope of this communication. A more complete review of all breech data has recently been published.[1] Several key issues and their key references will, however, be discussed in more detail.

Review of published data

Outcome comparisons of breech delivery and delivery in cephalic presentation, which may vary in magnitude, are nonetheless uniform in their results. For most of the important end points, infants born in breech presentation do worse than those in cephalic presentation. This comparison has been summarized by Seeds and Cefalo[2] (Table I). With this adverse outcome in mind, increasing use of cesarean section for breech delivery has occurred on the basis of the assumption that abdominal delivery would improve outcome. Major factors to be considered in analysis of this issue are: frank versus nonfrank breech presentation, the use of Piper's forceps, preterm breech delivery, and term breech delivery.

Table I. Risks associated with breech presentation

Fetal risk	*Approximate incidence*
Prematurity	16%-33%
Major anomalies	6%-18%
Birth trauma	13 times normal risk
Cord prolapse	5-20 times normal risk
Intrapartum asphyxia	3-8 times normal risk
Spinal cord injuries and deflexion	21%
Hyperextension of head	5%
Arrest of aftercoming head	8.8%

Modified from Seeds and Cefalo.[2]

Frank versus nonfrank breech

The observation has been made that nonfrank breech presentation is accompanied by increased perinatal mortality.[3] This observation has been used to justify the suggestion that patients with infants with nonfrank breech presentation not be allowed to labor. However, two important variables that affect outcome compound the analysis of nonfrank breech presentations—birth weight and cord prolapse.

Goldenberg and Nelson[4] have demonstrated that the proportion of breech deliveries that are nonfrank increases as birth weight decreases. They reviewed the records of 141 patients with breech presentation who were delivered vaginally. Their findings reveal, in infants weighing <2000 gm, that 66% of all breech presentations are nonfrank, whereas only 33% are frank. Consequently, data comparing frank and nonfrank presentations alone may include differences in birth weight distribution that will also affect outcome and survival. A second factor may also compound outcome analysis comparing frank and nonfrank breech presentation. Nonfrank breech presentations are associated with significantly more instances of cord prolapse.[2]

Table II. The low birth weight breech

Author	Years of study	Ratio of vaginal to cesarean deliveries	Survival ratio of vaginal to cesarean deliveries			Comments
			Birth weight			
			1000-1499 gm	1500-1999 gm	2000-2499 gm	
Woods[5]	1970-1975	61/16	35/75	0	0	Head entrapment ×7 in vaginal group. Respiratory distress syndrome cause of mortality in >50%
Karp et al.[3]	1970-1975	47/18	0	0	0	17% prolapsed cord in non-frank breech
Bowes et al.[8]	1970-1977	119/32	35/75	0	0	Includes 500-1500 gm birth weight since no difference with 500-999 gm documented
Duenhoelter et al.[9]	1972-1977	44/44	45/100	0	0	60% of deaths before 1974
Mann and Gallant[15]	—	279/157	0	0	0	No difference in 500-999 gm group. No difference in Apgar scores
Effer et al.[16]	1973-1980	67/95	0	0	0	No difference in 500-999 gm group
Gimovsky et al.[6]	1980	25/44	0/67	0	0	Similar for 500-999 gm group. Mortality only <1300 gm
Main et al.[11]	1977-1981	123/93	42/71	0	0	Includes 67 deliveries of 750-999 gm

Unless outcome analysis includes adjustments for these two potential biases, incorrect conclusions may follow.

Two studies that do not have the above biases have failed to demonstrate any difference in outcome for frank and nonfrank breech delivery. Woods,[5] in a retrospective review of 73 breech deliveries, failed to show any difference in outcome of frank or nonfrank breech delivery. He also failed to show any benefit of cesarean section for either group. Similarly, Gimovsky et al.,[6] in a prospective randomized study, failed to demonstrate a beneficial effect of cesarean section. In that study all infants with nonfrank breech presentation were randomized to either abdominal or vaginal delivery. The groups were comparable in birth weight and gestational age. No differences in the rate of mortality or trauma were demonstrated. In spite of these data, cesarean section continues to be recommended for nonfrank breech presentations.

Piper's forceps

Milner[7] has demonstrated that application of Piper's forceps to the aftercoming head will reduce neonatal mortality by one half in all birthweight groups. He observed a neonatal mortality of 162/1000 when Piper's forceps were not used, compared with 28/1000 when Piper's forceps were used. Moreover, this difference was still present when the data were analyzed by specific birth weight groups, for instance, for 1000 to 1499 gm birth weights, 22% mortality with forceps and 47% mortality without forceps.[7] Although these mortality figures are not directly comparable to more recent information, no published data refute Milner's conclusion. Despite this observation, reports of vaginal breech delivery continue without either discussion of the use of Piper's forceps or tabulation of frequency of their usage. It can only be stressed that the use of Piper's forceps be more routinely applied and reported.

Low birth weight breech

Perhaps the most controversial data regarding the effect of route of delivery on outcome are in the low birth weight breech group. Although fetopelvic disproportion does not occur, the possibility of head entrapment may be theoretically increased on the basis of the relatively larger head in a premature infant. Moreover, many authorities believe that premature infants are more susceptible to "trauma" during vaginal delivery. The eight most prominent studies covering this issue are summarized in Table II. Included in the table are the years in which the studies were performed, the total number of infants studied, and survivals in each of three birth weight groups. Inspection of these data reveals that no author was ever able to demonstrate a benefit of cesarean section in birth weights above 1500 gm, compatible with 30 to 31 weeks' gestational age, yet routine cesarean section generally is advocated for premature breech infants.

Very low birth weight breech

Data for the very low birth weight breech infant deserve further scrutiny. Studies of Woods,[5] Bowes et al.,[8] and Duenhoelter et al.[9] share a common flaw. In the early 1970s, the viability of infants weighing <1500 gm was clearly questioned. These three studies included

Table III. Mortality in very low birth weight breech deliveries (n = 37)

	Vaginal	*Cesarean section*	*Significance*
500-999 gm	12	9	
1000-1499 gm	3	13	
Mortality (%)	93	33	$p < 0.05$ (authors' data)
Sample <1000 gm (%)	80	41	$p < 0.05$ (our calculation)

Modified from Gimovsky et al.[6]

Table IV. Mortality in very low birth weight breech deliveries (n = 37)

	Vaginal	*Cesarean section*	*Significance*
750-999 gm	45/52	9/15	NS
1000-1249 gm	19/40	12/46	NS
1250-1499 gm	7/31	6/32	NS
No. of deaths/ Total No.	71/123 (58%)	27/93 (29%)	$p < 0.05$
Sample <1000 gm (%)	43	16	$p < 0.05$ (our calculation)

Modified from Main et al.[11]

patients who were delivered vaginally because they were thought in fact to carry previable infants. As an almost self-fulfilling prophecy, many of these infants subsequently died. Although cesarean section was occasionally carried out for maternal indications, it was usually only performed if the fetus was considered viable. Since the prognosis of viability was not prospectively controlled for in the management decisions of these three studies, the studies have to be considered of questionable validity and can be useful for comparative purposes only.

Two of the later studies (Table II) warrant further discussion. Gimovsky and Paul[10] reported a considerable benefit of cesarean sections in the very low birth weight group (Table III). However, 40% of deaths in their group delivered vaginally occurred in infants weighing <750 gm. Were these infants considered viable at Los Angeles County Hospital in 1980, or would they be considered as such even today? Moreover, the confounding effect of birth weight distribution differences between vaginal and abdominal groups was not considered. A significantly higher percentage of infants <1000 gm occurred in the vaginal group compared with the abdominal group (80% vaginal versus 41% abdominal; $p < 0.05$, our calculation). Surely the effect of birth weight on survival cannot be ignored. An identical error was made by Main et al.[11] (see Table IV).

Table V. Recommendations for breech delivery

Factors favoring vaginal delivery
- Birth weight <4200 gm
- Adequate pelvis
- Good progress of labor
- Absence of hyperextension of fetal head

Factors favoring cesarean section
- Birth weight >4200 gm
- Borderline pelvis
- Poor progress of labor (particularly descent) with adequate contractions
- Fetal distress
- Hyperextension of the fetal head

Although they correctly noted that there was no significant difference in survival in any of the three birth weight groups between 750 and 1500 gm, they chose to add the three weight groups together to come to the extraordinary conclusion that the vaginal delivery group did worse. In doing so, they failed to note that by lumping all three groups together, the vaginal group birth weights were skewed to those <1000 gm (43% under 1000 gm in the vaginal group versus 16% under 1000 gm in the cesarean group; $p < 0.05$, our calculation). Once again the confounding effect of birth weight on survival was interpreted as an effect of the route of delivery.

The most definitive data published to date on route of delivery for very low birth weight infants were recently presented by Kitchen et al.[12] from Melbourne. Their work included data on 326 infants born at 24 to 28 weeks' gestation between 1977 and 1982. Included in this group were 117 breech deliveries. The work of the Melbourne group stands out from all other published data for three major reasons. First, a prospective determination was made that all infants in the study were viable and consequently no infant's management was prejudiced by the expectation that the infant would die. Second, statistical analysis was performed with the use of a stepwise logistic regression analysis that took into account 14 different obstetric variables that could affect survival, including route of delivery. Last, and most important, half of the study infants were evaluated at 2 years of age with neurological and developmental assessments. We know of no other study of very low birth weight breech deliveries that includes these three crucial elements. The route of delivery was not prospectively randomized in the Melbourne study. It was assumed that vaginal delivery was safe and cesarean section was reserved for obstetric indications such as fetal distress and maternal disease. Only 16% of breech deliveries were by cesarean section. The authors found no difference between the two groups in either immediate or long-term outcome. Those advocating routine abdominal delivery for the very low birth weight

breech have no comparable data in support of their recommendation.

Term breech

Regarding term breech deliveries the two most significant studies for current obstetric practice are by Collea et al.[13] and Green et al.[14] Collea et al.[13] studied the outcomes of 208 patients with frank breech presentation at term in a prospective study with patients randomized to either vaginal or abdominal delivery. The conclusion of the authors was that vaginal delivery of the term frank breech was acceptable, provided patients fulfilled the minimum criteria of their study protocol.[13] There was no apparent advantage of cesarean section for the neonate. As expected, maternal morbidity was significantly greater in the abdominal delivery group.

A more provocative observation was made by Green et al.[14] in Montreal. When they retrospectively observed the outcome of 600 term breech deliveries during the period 1963 through 1973, they noted that birth trauma and birth asphyxia occurred in 18% of the deliveries. The cesarean section rate for that group was 22%. They reasoned that this incidence of birth trauma and birth asphyxia, which they considered unnecessarily high, could be reduced by the more liberal use of abdominal delivery. By 1978, they had been successful in increasing their cesarean section rate to 94% of all breech deliveries. Subsequent review of their data for 1978 and 1979 (n = 175) again indicated an incidence of birth trauma and birth asphyxia of 18%. This experience clearly demonstrates that the increase in cesarean section rate did not affect breech outcome.

The experience factor

It has been suggested that because today's obstetricians have inadequate experience with vaginal breech delivery, abdominal delivery represents a more prudent choice for "young practitioners." We reject this notion for several reasons. First, ignorance about the technique of breech delivery can result in trauma in both vaginal and abdominal delivery. A fetus will thus not benefit from abdominal delivery if the delivery technique used is inappropriate.

It is the profession's responsibility to provide training in breech delivery technique during the residency period. During this time a house officer has the opportunity to accumulate a concentrated, supervised experience, unmatched by any subsequent period of his or her professional life. The education of young physicians has to be the responsibility of senior obstetricians who have accumulated sufficient clinical experience in breech delivery to serve in a consulting capacity. Within such an educational framework, one could in fact foresee that these senior consultants will be available during vaginal breech deliveries at their institutions. Patients could thus be assured that breech deliveries are performed by the most experienced obstetrician in the safest way for mother and infant. After all, inexperience should never be the reason for a surgical solution. Experience is usually available.

Cost consideration

Cesarean section, compared with vaginal delivery, costs an additional $2700 per patient in hospital cost alone. Among 3.5 million deliveries per year in the United States, approximately 122,500 are in breech presentation. Currently, national cesarean section figures suggest that approximately 70% to 80% of all breech deliveries are performed by cesarean section. If the above-mentioned data from the Melbourne[14] and Montreal[16] groups are representative and a 20% cesarean section rate can safely be applied, 50% to 60% of breech deliveries (60,000 to 70,000 deliveries per year) are at present subjected to unnecessary cesarean sections. The annual national hospital cost for unnecessary cesarean sections for breech presentation thus approaches $200,000,000 per annum. These cost calculations do not include added costs for physician services, etc. Improved neonatal outcome could justify such cost. As should be evident, from the above-presented data, however, no such benefit exists.

Recommendation

On the basis of the review of obstetric literature, we suggest that previously held risk factors for vaginal delivery, such as nonfrank breech presentation, parity, and low or very low birth weight, are not associated with increased risk for birth trauma or birth asphyxia when vaginal delivery is compared with cesarean section. Patients presenting in labor with breech presentation must have the following: (1) ultrasound examination to exclude obvious anomalies, check placental localization, corroborate clinical estimate of fetal weight, and evaluate the angle between the cervical and thoracic spine; (2) clinical or x-ray pelvimetry if estimated fetal weight is >3500 gm or to corroborate hyperextension of the fetal head if ultrasound is unavailable or inadequate; (3) continuous electronic fetal monitoring; (4) adequate documentation of normal progress of labor. Should risk factors known to be associated with adverse outcome develop, cesarean delivery is to be used (see Table V). On the basis of the Montreal and Melbourne experience,[14, 16] the need for abdominal delivery should, however, not exceed 20% to 25% of all breech deliveries. Effective cesarean section monitoring programs for breech presentations therefore need to be developed. Such programs could include mandatory chart review and could be designed to tabulate which risk factors for vaginal breech delivery

have been documented on the chart. However, peer review can only be effective if a consensus develops in the professional's above-outlined guidelines. Most important, such an approach could be taken with confidence that no adverse effects on either mother or newborn infant would occur.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Immunoproteins in the endometrium: Clinical correlates of the presence of complement fractions C3 and C4

Delphine Bartosik, M.D., Ivan Damjanov, M.D., Ph.D., Richard R. Viscarello, M.D., and Judith A. Riley, M.D.

Philadelphia, Pennsylvania

The presence of complement fractions C3 and C4 in endometrial tissue was studied in a consecutive series of patients undergoing diagnostic laparoscopy, to determine their specific association with endometriosis. The incidence of complement in eutopic endometrium of patients grouped according to four diagnoses was: endometriosis, 66% positive (23 of 35); active pelvic inflammatory disease, 85% positive (11 of 13); combined endometriosis with pelvic inflammatory disease, 25% positive (one of four); laparoscopically normal pelvis, 67% positive (10 of 15). These differences were not statistically significant. Complement was equally likely to be found in proliferative, secretory, menstrual, or inflammatory endometrium. Endometrial complement was found less frequently in patients with severe endometriosis as compared with those with the mild form. Among patients with endometriosis and infertility, complement was much more likely to be found in patients with primary infertility than in those with secondary infertility ($p < 0.007$). In short-term follow-up of these patients, the absence of complement in the eutopic endometrium appeared to be a good predictor of subsequent pregnancies. (Am J Obstet Gynecol 1987;156:11-5.)

Key words: Endometriosis, pelvic inflammatory disease, complement, immunoglobulins, endometrium, infertility, autoimmune phenomena

Weed and Arquembourg[1] reported that the complement fraction C3 was found in the eutopic (uterine) endometrium of patients with endometriosis but was absent from control subjects. On the basis of these observations, they formulated the hypothesis that endometriosis is an autoimmune disease. However, no other studies of the specificity of this phenomenon have been reported. Therefore we studied a consecutive series of patients for the presence of complement fractions C3 and C4 in the uterine endometrium. Our observations are the subject of this report.[2]

Material and methods

Patient population. All patients in whom laparoscopy with endometrial biopsy was performed during a 4-month period were included in this study. There were a total of 67 patients. Clinical indications for performing laparoscopy are summarized in Table I. Thirty-two patients had either primay or secondary infertility and 47 patients had pelvic pain. There were 11 other pa-

tients in whom the indications for laparoscopy were: evaluation of a pelvic mass (seven), laparoscopic tubal sterilization (two), and evaluation for tubal reanastomosis (two). Laparoscopy was performed in the standard manner with a second puncture probe used to permit visualization of all pelvic peritoneal surfaces.

Immunofluorescence microscopy.[3] The endometrial tissue was placed in sodium chloride, 0.15 mol/L transferred to the laboratory, frozen in liquid nitrogen, and embedded in OCT (Lab Tek, Naperville, Indiana). Sections of 8 μm were cut on a cryostat, postfixed in cold (4° C) acetone for 10 minutes, rehydrated, and processed further for incubation with the antibody. All incubations were performed in a moist chamber at room temperature for 1 hour. The fluorescein isothiocyanate–labeled antisera raised in goat or rabbit to human complement fractions C3 and C4 were purchased from Cappel Laboratories, Cochranville, Pennsylvania. Ratios of fluorescein to protein varied from 1.6 to 3.9. Monospecificity of the antisera was determined by immunoelectrophoresis and by Ouchterlony double diffusion. The optimal dilution for direct immunofluorescence staining was determined by titration on an open renal biopsy specimen known to contain deposits of immunoglobulin and complement and varied, in general, from 1 : 10 to 1 : 30. The same renal tissue was used as a positive control run in parallel in all endometrial specimens. The controls included tissue sections incubated with the same antibodies, but not labeled with fluorescein isothiocyanate or preabsorbed with human complement or simply with fresh human plasma. The preabsorbed antiserum was found to be unreactive with the "positive control," the kidney biopsy specimen as described above. Coverslips were applied, and the slides were mounted with glycerol and examined with a Leitz microscope outfitted with ultraviolet epiillumination.

The findings were subjectively evaluated and graded either as negative or as mild, moderate, or strongly positive (0 to 3). The reactivity of the uterine glandular epithelium, stroma, and vessels were evaluated separately. The diagnoses were not available to the pathologist when the slides were evaluated.

Routine histologic evaluation. Sections of the remaining endometrial tissue were fixed in 10% formaldehyde and stained with hematoxylin and eosin.

Statistical analyses. All comparisons of the prevalence of complement within the several diagnostic categories were analyzed by χ^2 tests.

Results

Immunofluorescence microscopy. Examples of endometrial tissue showing the presence of C3 are illustrated in Figs. 1 to 3. Fig. 1 illustrates C3 in the glandular epithelium of the endometrium. Fig. 2 illustrates C3 directly under the surface of the endometrial lining. Fig. 3 illustrates C3 around the glandular basement membranes and in the stroma. Microscopy of C4 immunofluorescence in the endometrium was similar to the figures presented for C3.

We were unable to determine a disease-specific pattern of C3 or C4 within the morphologic subsets of endometrium, that is, glands, basement membranes, or stroma. Subsequent analyses were therefore tabulated either as positive or as negative.

Incidence of complement in the uterine endometrium. Sixty-seven percent of all patients had either C3 or C4 in the uterine endometrium. With analysis according to laparoscopic diagnosis, 66% (25 of 35) of patients with endometriosis, 85% (11 of 13) of patients with pelvic inflammatory disease, 25% (one of four) of patients who had both endometriosis and pelvic inflammatory disease, and 67% (10 of 15) of patients with a laparoscopically normal pelvis had either C3 or C4 in the uterine endometrium. These data are presented in Table II.

Association between the presence of complement and the stage of endometriosis. Patients with endometriosis had staging done according to the criteria

established by the American Fertility Society.[4] Among patients with endometriosis, there appeared to be a negative correlation between the stage of endometriosis and the incidence of complement. Thus 79% (15 of 19) of patients with Stage I, 50% (five of 10) of patients with Stage II, and 40% (three of five) of patients with Stage III endometriosis had demonstrable complement in the uterine endometrium. However, these differences were not statistically significant.

Association between endometrial histologic features and the presence of complement. The association between endometrial histologic features and the presence of C3 and/or C4 in the uterine endometrium is presented in Table III. Results of classical endometrial histologic features were not available in all patients, because if the amount of tissue obtained at biopsy was small, most of the tissue was subjected to immunologic analysis. We observed C3 and/or C4 in 17 of 23 samples (74%) of uterine endometrium in the proliferative phase, 13 of 18 samples (72%) in the secretory phase, three of four samples (75%) in the menstrual phase, and four of six samples (67%) with endometritis. Thus there does not appear to be any difference in the likelihood of the occurrence of C3 or C4 in the uterine endometrium obtained from different hormonal or inflammatory environments.

Association between infertility and the presence of complement. Among all patients, regardless of diagnosis, endometrial complement was slightly more likely to be found in patients with primary infertility. These data are summarized in Table IV. However, among the patients with endometriosis alone, endometrial C3-C4 was much more likely to be found in the group of patients with primary infertility than in those with secondary infertility. Ten of the 11 patients with endometriosis and primary infertility had endometrial complement, whereas only five of the 10 patients with secondary infertility had endometrial complement. These differences were statistically significant ($p < 0.007$).

In short-term follow-up of this group of patients, four patients with Stage I endometriosis became pregnant. None had endometrial complement.[2] Among all patients with Stage I endometriosis, 79% had endometrial complement.

Comment

The purpose of this study was to determine whether complement (C3 or C4) could be found in the eutopic (uterine) endometrium of patients with endometriosis and be absent from the endometrium of other patients. In contrast to the report of Weed and Arquembourg,[1] we observed that complement in the eutopic endometrium is not specific for patients with endometriosis. Endometrial complement was found among patients with pelvic inflammatory disease and in patients with a laparoscopically normal pelvis. For the purposes of this report, a laparoscopically normal pelvis is defined as one with neither endometriosis nor pelvic inflammatory disease. However, this group of subjects included a disproportionate number of patients with infertility and/or pelvic pain. Among the latter, most of the women either were not sexually active or were using barrier methods of contraception. Therefore, one cannot judge their fertility potential. Future studies must include a larger group of normal women, of established fertility (delivery within the previous year), who are requesting tubal sterilization. This would allow us both to inspect for the presence of endometriosis and to perform endometrial biopsies to quantify endometrial complement.

In two well-established in vitro fertilization pro-

grams, there were diametrically opposite results in terms of pregnancies among patients with endometriosis: The Norfolk group[5] showed high pregnancy rates, similar to those of their patients with tubal disease, while the British workers[6] showed significantly reduced pregnancy rates. The discrepancy may be due to the fact that most patients in the Norfolk group had undergone treatment for endometriosis while most of the British patients had received no therapy. Wild and Shivers[7] observed endometrial autoantibodies in the sera of 82% of patients with infertility and endometriosis. Although the presence of endometrial complement per se is nonspecific, it may be that complement-fixed endometrial autoantibodies are causally related to the infertility of some endometriosis patients. Such complement-fixing autoantibodies could induce a cytolytic, antiimplantation effect in the endometrium. This hypothesis would explain our observation that, in short-term follow-up, none of the patients with Stage I endometriosis who became pregnant had endometrial complement.

We also observed, among patients with endometriosis, that endometrial complement was more prevalent in patients with primary infertility than in those with secondary infertility. Possible explanations include a higher incidence of complement-fixing autoantibodies or a higher incidence of nonspecific endometrial complement in the primary infertility group. Whatever the explanation, it would seem prudent to view such patients (that is, primary versus secondary infertility) as separate subgroups of the total population of endometriosis-infertility patients.

In conclusion, although the presence of endometrial complement is a nonspecific finding, the data presented and reviewed support the hypothesis of Weed and Arquembourg[1] that endometriosis is an autoimmune disease. However, considerably more research must be done to confirm, extend, and interpret this hypothesis.[8]

Labial fusion in prepubescent girls: A marker for sexual abuse?

Carol D. Berkowitz, M.D., Sandra L. Elvik, R.N., B.S.N., C.P.N.P., and Mary K. Logan, R.N., B.S.N., P.H.N.

Torrance, California

Review of more than 500 medical records of patients referred for sexual abuse evaluations revealed 10 cases of labial fusion. Patients ranged in age from 2 months to 5 years, and the duration of the fusion ranged from 2 weeks to 2½ years. No child had vulvovaginitis, dermatitis, or known genital trauma (for instance, straddle injury). Urinary tract problems were present in three patients. History and/or physical findings were consistent with sexual abuse in six of the 10 patients. Anal findings were grossly abnormal and consistent with anal penetration in all patients with a positive finding on examination. Therapy with conjugated estrogen cream was instituted in nine patients, with resolution of symptoms occurring in six. The exact cause of labial fusion is unclear. Fusion secondary to fecal soiling may occur in the young infant. Older girls may develop fusion after trauma such as that associated with sexual abuse, particularly vulvar coitus. (AM J OBSTET GYNECOL 1987;156:16-20.)

Key words: Labial fusion, vulvar fusion, labial agglutination, sexual abuse, child abuse

Labial fusion is defined as either partial or complete adherence of the labia minora.[1] Other names for this condition include vulvar fusion, synechiae of the vulva, adhesions of the labia minora, and agglutination of the labia minora.[2] The disorder occurs in prepubescent girls and has been reported in postmenopausal women (senile adherent vaginitis).[3] While the literature states that labial fusion is a frequent occurrence, the prevalence of the condition in the pediatric population is uncertain. Huffman reports the greatest incidence in girls 2 to 6 years old, while others note the highest frequency in infants under 2 years of age.[1, 4-6] Ben-Ami et al.[1] found in a prospective study that the condition was not present at birth but subsequently developed in nine of 1500 newborn infants followed up for 3 years, an incidence of less than 1%.

We recently began evaluating large numbers of children believed to have been sexually abused. During the course of these assessments, we became aware of a higher frequency of labial fusion than we had previously noted. In addition the patients seemed older than the infants with labial fusion we had previously encountered. We reviewed cases of sexual abuse retrospectively and describe our experience with labial fusion in a population of prepubescent girls undergoing evaluation for sexual abuse.

Methods and material

All patients were evaluated in the Pediatric Clinic of Harbor/University of California Los Angeles Medical Center in Torrance, California, a large, county-funded teaching hospital affiliated with the University of California Los Angeles School of Medicine. There are approximately 40,000 outpatient visits per year with 60 to 80 children seen per month for suspected sexual misuse. Patients are referred from numerous agencies, including law enforcement, protective services, juvenile court, community pediatricians, and psychologists.

Charts of all patients referred for sexual abuse evaluations between January and October 1985 were reviewed retrospectively to detect patients with labial fusion. The diagnosis of labial fusion was made on clinical grounds, on the basis of a thin line of adherence between the labia minora.[4] Patients were examined with simple visual inspection and with a colposcope by one or two of the authors. Records of patients with labial fusion were studied in detail, and the following information was noted: patient's age, degree of labial fusion, duration of labial fusion (if known), history and physical findings consistent with sexual misuse, history of trauma, urinary tract infections, or masturbation, other physical findings (particularly evidence of seborrheic or atopic dermatitis), therapeutic interventions, and follow-up evaluation.

Table I. Characteristics of patients with labial fusion

Case No.	*Age*	*Fusion (%)*	*History of sexual abuse*	*Results of physical examination**	*Urinary findings*	*Treatment†*	*Outcome*
1	5 yr	Complete	+	Hymen, normal Anal, abnormal	0	+	Partial resolution
2	4 yr	Partial	+	Hymen, not visualized Anal, abnormal	+	+	Partial resolution
3	5 yr	Complete	+	Hymen, normal Anal, abnormal	0	+	Partial resolution
4	4 yr	Complete	+	Hymen, not visualized Anal, abnormal	0	+	No follow-up

Results

Five hundred charts were reviewed. Seventy-five percent of the patients were female. Ten cases of labial fusion were detected, representing an incidence of about 3%. Table I summarizes these cases.

Patients ranged in age from 2 months to 5 years. Complete labial fusion with only a small anterior aperture was noted in seven (70%) and partial fusion involving only the posterior portion in three (30%) (Fig. 1). The duration of fusion could be estimated in five (50%) patients and ranged from 2 weeks to 2½ years. No patient had a specific history of trauma (for instance, straddle injury) other than related to sexual misuse. A history of masturbation was noted in one (Case 1). Masturbation was reported to occur on a daily basis and consisted of vigorous genital rubbing. Urinary tract symptoms were reported in three children. Two patients (Cases 2 and 4) had a history of urinary incontinence, and urinary reflux into the vagina was noted during voiding. One patient, 12 months old, had a documented urinary tract infection with *Enterobacter cloacae* that responded to ampicillin. No patient had a history of recurrent urinary tract infections.

Laboratory studies (urinalysis, urine culture, rectal and oral culture for *Neisseria gonorrhoeae*) were negative in all patients studied except for the child with the urinary tract infection. Two children (Cases 1 and 5) had vaginal cultures for chlamydia, and these were negative. No child had cultures taken for *Gardnerella*. The physical examination, apart from the genital and anal findings, was normal in all patients. No patient had physical evidence of seborrheic or atopic dermatitis.

Findings consistent with sexual abuse were noted in six patients. Four patients had both a history and a physical examination consistent with sexual abuse. One patient (Case 5) gave a history of sexual abuse, but there were no physical findings. In each case, the history was obtained from the accompanying caretaker or from the patient after extensive interviews. Physical findings consistent with sexual abuse were observed in five patients, including one patient who gave a negative history. Anal findings were grossly abnormal and consistent with anal penetration in all patients with a positive examination. Abnormal anal findings included lax anal tone in five (Cases 1, 2, 3, 4, and 6), transections of the external anal sphincter in two (Cases 3 and 4), and perianal tag in one (Case 2). The hymenal area was adequately visualized in six children and was abnormal in only one (Case 4). Examination of this girl showed an enlarged introitus with absent hymenal remnant. All four patients with no findings of sexual abuse were under 14 months of age.

Nine patients (90%) were treated with conjugated estrogen cream. Resolution of the labial fusion occurred in six. Two patients did not return for follow-up. Three patients experienced breast hypertrophy, which led to cessation of therapy. Other side effects of the estrogen included labial pigmentation and the appearance of fine, downy labial hair. Re-fusion after cessation of therapy was noted in one patient who was followed up for a year. This was the child who exhibited

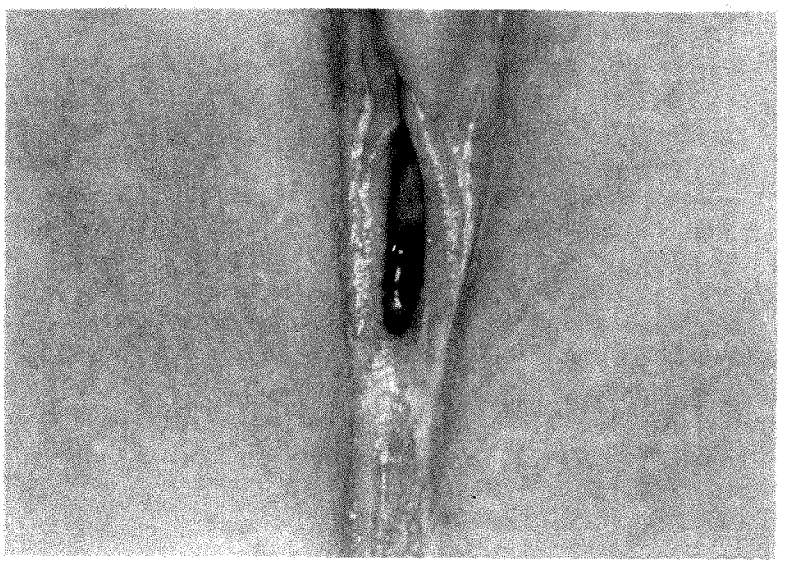

Fig. 1. Partial fusion of the labia minora in a 4-year-old Hispanic girl (Case 6).

daily masturbation. No patient had spontaneous resolution of the labial fusion during the study period.

Comment

Although the exact cause of labial fusion is unknown, a variety of disorders have been associated with the development of this condition. In the neonatal period, it may be seen with anatomic abnormalities, such as congenital absence of the vagina or ambiguous genitalia.[7] Ambiguous genitalia may indicate significant disease processes, such as true hermaphroditism, pseudohermaphroditism, or congenital adrenal hyperplasia. Labial fusion is an incorrect term in these conditions because labioscrotal folds are present. Exposure to excessive androgens results in failure of separation of the tissues of the perineal body between the urogenital sinus and the anus. Androgenic stimulation in the female fetus between the ninth and thirteenth weeks of gestation results in posterior adhesion of the labia along with clitoromegaly; after the thirteenth to fourteenth weeks of gestation, androgen exposure produces clitoromegaly alone. Labial fusion without clitoromegaly has been reported infrequently with congenital adrenal hyperplasia.[8]

Because fusion should be distinguished from failure of separation, Nowlin et al.[4] qualify the definition of labial fusion as "acquired post-inflammatory cohesion of the labia minora." The underlying mechanism is the denuding of the upper squamous epithelial layer of the labial mucosa with subsequent formation of a connective tissue bridge between the healing labia. Normally low estrogen levels in the prepubescent girl predispose to labial adhesions.[4-6] Adequate endogenous estrogens change the vaginal epithelium from a thin atrophic lining to a thick one containing glycogen.[3] In addition the neutral pH of the vaginal secretions in the prepubescent girl predisposes to inflammation and infection.[6]

Vulvovaginitis has been implicated in the formation of adhesions, although this relationship has not been systematically studied. Accurate vaginal cultures are difficult to obtain in the face of labial fusion, and there is usually no leukorrhea.[2] There are multiple causes of vulvovaginitis. Most cases are secondary to "poor hygiene," such as improper wiping techniques and playing in dirty sandboxes.[6] In the infant, feces and urine in the perineal area, as well as occlusive diapers, may inflame the labial mucosa and lead to fusion.[5] Nowlin et al.[4] reported no cases of fusion secondary to gonococcal infection or "frank nonspecific vulvitis." Likewise, Bowles and Childs[2] had no cases in which there was a history of vulvitis, vaginitis, trauma, or severe injury. Nonspecific vaginitis has recently been reported with *Gardnerella*.[9] Neither Nowlin et al. nor we performed cultures for *Gardnerella*. No child in our series had an antecedent history of vulvitis, and cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* were negative. Vakar,[10] on the other hand, reported vulvovaginitis in 47% of his cases, although some of these had "physiologic desquamative vulvovaginitis" of the newborn infant. In this condition the neonatal mucosa is felt to be particularly vulnerable to invasion by stool flora.

Children with seborrheic dermatitis may experience recurrent vulvitis.[6] Such children are particularly prone to candidiasis. Atopic eczema infrequently leads to inflammation of the vulva. No patient in our series had evidence of either of these conditions, and fusion sec-

ondary to atopic or seborrheic dermatitis is reported in a minority of patients.[6]

A wide assortment of acute infectious illnesses has been implicated. These include cholera, diphtheria, scarlet fever, pneumonia, and typhoid fever.[11] Measles and chickenpox may produce lesions in the vulva and vagina with subsequent fusion.[6] No patient in our series had any of these conditions.

The role of trauma in the development of labial fusion has not been previously explored. Taylor[12] reported the case of a child with labial fusion after a "picket fence injury." No child in our series had a history of a straddle or picket fence injury. One would not expect such injuries to traumatize the labia minora.[2] The mechanism of a straddle injury is such that the labia majora and/or periurethral structures are crushed between the pelvic bone and an external object. Vigorous masturbation may lead to denuding of the labial mucosa and predispose to fusion. Self-stimulation is usually around the clitoris since this is the area of greatest sensation. Diffuse rubbing around the labia minora may occur with autostimulation or vulvar coitus. The latter is a form of sexual activity in which the penis is rubbed back and forth between the labia. It is possible that fusion may occur after such frictional irritation.

Eliciting a history of sexual abuse in the prepubescent child may be difficult. Children are often reluctant to disclose such information. They may say that the molestation happened to someone else. Interviews are facilitated by the use of anatomically correct dolls, puppets, or crayons and paper. In addition the disclosure may be recanted at a subsequent time or to another individual.

Diagnosing sexual abuse on the basis of the physical examination is dependent on the presence of abnormal genital and/or anal findings. Changes in the genital area that are consistent with sexual abuse include tears, scars, and distortion of the hymen, with the presence of synechiae and neovascularization.[13] The presence of labial fusion obscures these findings, and necessitates the institution of treatment to allow adequate visualization of the hymenal area.

Anal findings may be absent in 50% of individuals who are either acutely or chronically sodomized. Changes of long-standing, chronic sodomy include perianal scars that are wider on the outside and taper inward, tags, changes in the appearance of the anal folds, thickening and hyperpigmentation of skin in the perianal area, loss of perianal adiposity, funneling, laxity of tone, and loss of the anal "wink."[13, 14] These changes were noted in five patients in this study.

All four children with no physical findings of sexual abuse were infants. In two there was some suspicion about molestation. One infant (Case 7) had failure to thrive, was from a chaotic household, and had been removed from the home. The second infant (Case 8) was brought in by the mother because of concern that the infant may also have been molested after an examination of the 7-year-old sister revealed findings consistent with sexual misuse. The two remaining infants had been referred for genital evaluation because of the presence of the labial fusion.

Urinary symptoms occurred in two (20%) of our patients. Others[1, 4, 15] report an incidence of urinary symptoms with labial fusion from 20% to 50%. Usual symptoms including infection, incontinence, dribbling, and tenesmus are secondary to interference with urinary outflow.[4, 11] Marked reflux of urine into the vagina with trapping of the urine above the fused labia has been demonstrated with contrast material during voiding cystourethrography.[1] Because of the high frequency of urinary symptoms, urinalysis and urine culture appear warranted in the evaluation of labial fusion.

Treatment with estrogen cream will relieve the fusion in about 90%.[5] Treatment is usually not necessary because the fusion will resolve spontaneously at puberty.[1] Jenkinson and Mackinnon[16] reported spontaneous resolution in 10 infants under 2 years of age followed up for 18 months. Early intervention is recommended if urologic symptoms exist or there is a need for adequate visualization of the hymenal area. Treatment is not without side effects, such as breast engorgement, and the labia may re-fuse with cessation of therapy. Surgical separation of the fused labia, which has been advocated by some investigators, is rarely needed, is unnecessarily traumatic, and carries a high incidence of recurrence.[5, 11]

In conclusion labial fusion is a disorder of adhesion of the labia minora. It may occur secondary to a variety of inflammatory conditions including vulvovaginitis or seborrheic or atopic dermatitis. In young infants, fecal soiling and diaper dermatitis may promote the condition. In older girls, trauma such as that associated with sexual abuse may predispose to labial fusion. The finding of labial fusion in the older girl warrants a careful anal examination and a disclosure interview by skilled personnel to determine if there is a history of sexual abuse.

Postmenopausal smoking, estrogen replacement therapy, and the risk of endometrial cancer

Adele L. Franks, M.D., Juliette S. Kendrick, M.D., Carl W. Tyler, Jr., M.D., and The Cancer and Steroid Hormone Study Group*

Atlanta, Georgia

Previous studies of the association between cigarette smoking and endometrial cancer have yielded inconsistent results. There is some evidence that this discrepancy may be explained by differences in menopausal status between the groups of women studied. We addressed the issue of the effects of postmenopausal smoking on endometrial cancer risk using data from the Cancer and Steroid Hormone Study, a multicenter, population-based, case-control study of gynecologic cancers in the United States. We found that smoking after natural menopause is associated with a 70% reduced risk of endometrial cancer among estrogen users and a 50% reduced risk among nonusers of estrogen. These findings are consistent with previously proposed biologic effects of smoking on estrogen metabolism, which may have important clinical implications. (Am J Obstet Gynecol 1987;156:20-3.)

Key words: Endometrial cancer, estrogen replacement therapy, smoking, estrogen metabolism

It is now widely agreed that endometrial cancer is associated with estrogen stimulation of the endometrium.[1-3] Several studies have shown that women who smoke have earlier menopause,[4-6] an increased risk of osteoporosis,[7-9] and decreased urinary estrogens,[10] suggesting that smokers have reduced estrogen. Thus, since there is no evidence for a direct carcinogenic effect of cigarette smoking on the endometrium, smokers might be expected to have a reduced risk of endometrial cancer by virtue of diminished estrogen stimulation.

Reprints are not available.
**Individual members of the study group are listed at the end of the article.*

Previous studies of this relationship have yielded inconsistent results, and only three studies have controlled for important potential confounding factors.[11-13] Weiss et al.[11] found a significant negative association between "ever smoking" history and endometrial cancer (relative risk = 0.4, 95% confidence interval = 0.2 to 0.7), whereas Tyler et al.[12] found a slightly lowered risk which was not statistically significant (relative risk = 0.8, 95% confidence interval = 0.7 to 1.1). Both studies showed that cigarette smoking reduced the elevated risk of endometrial cancer among women who used estrogens. Since Weiss et al. studied women 50 to 74 years old and Tyler et al. studied women 20 to 55 years old, the difference in smoking effect may be related to factors that are age dependent, in particular, to menopausal status.

A recent study by Lesko et al.[13] has suggested that menopausal status may be an important modifier of the effects of smoking. They found a significantly reduced risk of endometrial cancer (relative risk = 0.5, 95%

confidence interval = 0.3 to 0.8) among women who were currently smoking at least 25 cigarettes per day. When premenopausal and postmenopausal women were considered separately, the protective effect of smoking was confined to the postmenopausal women. The effect of smoking in relation to exogenous estrogen use was not reported.

To address the hypothesis that both postmenopausal smoking and postmenopausal estrogen use affect endometrial cancer risk, we analyzed data from a subset of women enrolled in the Cancer and Steroid Hormone Study. The previous analysis[12] used the entire data set to address the question of cumulative lifetime effects of cigarette smoking and did not consider the temporal relation of smoking to menopause.

Material and methods

The details of this study have been described elsewhere.[12, 14] Cases were women who were 20 to 55 years old with histologically confirmed epithelial endometrial cancer newly diagnosed between December 1, 1980, and December 31, 1982, in six geographic areas (two of the original eight centers did not participate in the histologic review). Controls were women of the same age range identified by calling randomly selected telephone numbers from the same geographic areas as the cases. For this analysis we selected only postmenopausal women over the age of 40 (106 case subjects, 528 controls). These were women who had undergone a natural menopause, and whose last menstrual period occurred after the age of 40 and at least 6 months before diagnosis or interview. (This excluded perimenopausal women, who were included in the postmenopausal category in the previous analysis).

Postmenopausal smoking was defined as smoking cigarettes after the last menstrual period, regardless of when smoking began. Women who stopped smoking before menopause were excluded (17 cases, 87 controls). Postmenopausal estrogen replacement therapy was defined as first use of noncontraceptive estrogen beginning after age 40 and continuing after the last menstrual period. Women whose only use of noncontraceptive estrogen occurred before menopause were excluded (10 cases, 25 controls). This left 495 women (79 cases, 416 controls) for analysis. Nonsmokers were women who reported having smoked less than a total of 100 cigarettes in their lifetime, and nonusers of estrogen replacement therapy had never used noncontraceptive estrogens for 3 consecutive months or more.

Logistic regression was used to derive odds ratios (as relative risk estimates) and confidence intervals[15] for the exposures of interest. Relative risk estimates were adjusted both individually and simultaneously for the following factors considered a priori to potentially confound the results: age and age at menopause (as continuous variables), race, Quetelet's adiposity index (weight/height squared), hypertension, diabetes, infertility, parity, history of oral contraceptive use, and geographic region (as categorical variables). None of these adjustments appreciably altered the risk estimates. Therefore the unadjusted relative risk estimates are presented, with test-based confidence intervals.[16]

To evaluate the possible modification of smoking effects by previous oral contraceptive use or obesity, data were stratified according to these factors.

Table I. Selected characteristics of postmenopausal endometrial cancer cases and controls

*Weight (kg)/[height (cm)]^2.

Results

Cases were more likely than controls to be older, white, nulliparous, obese, and hypertensive and to have never used oral contraceptives (Table I). Smoking after menopause was associated with a significantly reduced risk of developing endometrial cancer, with smokers having half the risk of nonsmokers (Table II). When stratified by use of estrogen replacement therapy (Table III), a similar smoking effect was present both among nonusers and users of estrogen replacement therapy (reference group 1 column). Smokers who did not use estrogen replacement therapy had a 50% reduction in endometrial cancer risk compared with nonsmokers, whereas smokers who did use estrogen replacement therapy had a 70% reduction in risk.

The separate effects of single or joint exposures to postmenopausal smoking and estrogen replacement therapy, compared with exposure to neither, can be seen in the reference group 2 column in Table III.

Table II. Epithelial endometrial cancer risk associated with postmenopausal smoking

Smoking status	*Cases*	*Controls*	*Relative risk*	*95% Confidence interval*

Postmenopausal smokers	29	228	0.5	0.3-0.8

Table III. Epithelial endometrial cancer risk associated with postmenopausal smoking, stratified by postmenopausal estrogen replacement therapy

Estrogen replacement therapy and smoking status	*Cases*	*Controls*	*Reference group 1**		*Reference group 2†*	
			Relative risk	*95% Confidence interval*	*Relative risk*	*95% Confidence interval*
Nonusers of estrogen replacement therapy						
Nonsmokers	37	172	1.0	Referent	1.0	Referent
Postmenopausal smokers	23	200	0.5	0.3-0.9	0.5	0.3-0.9
Postmenopausal estrogen replacement users						
Nonsmokers	13	16	1.0	Referent	3.8	1.7-8.2
Postmenopausal smokers	6	28	0.3	0.1-0.8	1.0	0.4-2.6

*Based on nonsmokers in each estrogen replacement therapy category as reference group.

†Based on nonsmokers who were nonusers of estrogen replacement therapy as reference group for all comparisons.

Women who used estrogen replacement therapy but did not smoke had a significantly elevated risk (relative risk = 3.8) of endometrial cancer. Women who used estrogen replacement therapy and smoked had the same risk as the nonusers who did not smoke (relative risk = 1.0).

We were unable to evaluate the risk of endometrial cancer according to daily dose of cigarette smoking after menopause, because the only dose information acquired was the lifetime daily average number of cigarettes smoked. There was no consistent trend in endometrial cancer risk according to lifetime average amount smoked each day.

Stratification by obesity and previous oral contraceptive use revealed no appreciable stratum-specific differences in the effects reported.

Comment

Our results show that smoking cigarettes after natural menopause is associated with a decreased risk of developing endometrial cancer for postmenopausal women 40 to 55 years old. The increased risk of endometrial cancer associated with postmenopausal estrogen replacement therapy is reduced in postmenopausal smokers in such a way that women with both exposures have the same risk as women with neither.

Despite the relatively small number of postmenopausal women in our study, our findings are consistent with previous research.[11, 13] We do not believe confounding accounts for our findings, since adjustment for known endometrial cancer risk factors did not alter our results.

The protective effect of smoking emerged more clearly in a subset of women who smoked after natural menopause than in the larger group of women with unspecified exposure intervals.[12] Comparison of currently smoking premenopausal women (22 cases, 474 controls) with nonsmoking premenopausal women (50 cases, 753 controls) yielded a smaller reduction in risk which was not statistically significant (relative risk = 0.7, 95% confidence interval = 0.4 to 1.2). Because premenopausal women are a hormonally heterogeneous group, their risk of endometrial cancer may not be uniformly affected by smoking.

Baron[17] has suggested that the antiestrogenic effects of smoking in women may be mediated by induction of hepatic microsomal enzymes similar to those induced by smoking in laboratory animals.[18] Our data are consistent with an antiestrogenic smoking effect among postmenopausal users of exogenous estrogen replacement therapy. This supports the possibility of a peripheral, and extraovarian, biologic mechanism such as induction of estrogen metabolizing enzymes. Such a peripheral mechanism may be operative only while the inducing exposure is present. Thus the antiestrogenic effect of cigarette smoking may be reversible after cessation of smoking. In our data, postmenopausal women who quit smoking before menopause (and thus were excluded from the data shown) had a diminished endometrial cancer risk intermediate between, but not significantly different from, the nonsmokers and postmenopausal smokers (compared with nonsmokers relative risk = 0.7 and 95% confidence interval = 0.4 to 1.3).

Even with evidence that cigarette smoking is associated with a significantly reduced risk of endometrial

cancer among postmenopausal women, women should not smoke for this or any other reason, in view of the serious morbidity and mortality of common smoking-attributable diseases.

We believe, however, that such findings have potentially important clinical implications. There is mounting evidence to suggest that use of estrogen replacement therapy by postmenopausal women decreases their risk of ischemic heart disease[19, 20] and osteoporosis[8, 9, 21-23] and that these protective effects are at least in part dose dependent. The finding of this analysis and others,[11, 13] that postmenopausal smoking is associated with decreased estrogen effects on the endometrium, is consistent with smoking-induced enhancement of estrogen metabolism. By such a mechanism, smoking may also diminish the effects of estrogen on other end organs such as coronary arteries and bone.[8] If so, postmenopausal women who cannot be persuaded to stop smoking may need higher doses of estrogen than nonsmokers to achieve comparable therapeutic effects.

The efficacy of intrapartum electronic fetal monitoring

Stephen B. Thacker, M.D.
Atlanta, Georgia

With basic methodologic criteria as a framework, this report assesses the quality of the seven randomized controlled clinical trials conducted in five countries to compare a policy of routine electronic fetal monitoring with a policy of fetal heart rate monitoring by auscultation. One trial found a statistically significant decrease in the occurrence of neonatal seizures in the electronic fetal monitoring group. The trials demonstrated no other statistically significant benefit associated with the use of electronic fetal monitoring, but most reported significant increases in the rates of abdominal and vaginal operative deliveries associated with electronic fetal monitoring. Taken together, the seven trials provide valuable information about the routine use of intrapartum electronic fetal monitoring; they do not demonstrate that it is a useful screening procedure for all women in labor. (Am J Obstet Gynecol 1987;156:24-30.)

Key words: Electronic fetal monitoring, randomized controlled trials

A 1979 literature review on the efficacy and safety of electronic fetal monitoring coauthored by Banta and Thacker[1] concluded that there was insufficient evidence at that time to recommend the routine use of electronic fetal monitoring. In addition, we concluded that there was low predictive value positive for electronic fetal monitoring, a high cost to the individual and society, and a premature diffusion of this technology into routine clinical practice. Four randomized controlled clinical trials completed at that time failed to demonstrate a decrease in morbidity and mortality associated with the use of electronic fetal monitoring but did show a twofold increase in the rate of cesarean delivery among patients monitored electronically.[2-5] Because the available evidence suggested a possible benefit for the use of electronic fetal monitoring in selected high-risk pregnancies, we recommended that randomized controlled clinical trials be undertaken to test that hypothesis.

The randomized controlled clinical trial is generally accepted as the ideal method to assess the efficacy of clinical interventions in human populations.[6] As with any human endeavor, however, trials are subject to flaws in conduct and errors in implementation.[7] This report systematically assesses the seven randomized controlled clinical trials conducted to date to evaluate the routine use of electronic fetal monitoring[2-5, 8, 9] (Neldam S, Osler M, Hansen P, et al., unpublished observations).

Assessing a clinical trial

Understanding of the 12 criteria given in Table I is essential to adequate interpretation of the conduct and analysis of an randomized controlled clinical trial.[10, 11] In the completion of Table I, an effort was made to obtain previously unpublished information from the authors to give a more complete picture of the available knowledge.

Prior hypotheses and statistical power. Greatest emphasis should be given to results related to those hypotheses for which a study is designed. Prior hypotheses were precisely stated only in the Dublin trial, although general goals were implicit in the other six. Statistical power (the probability that a study will detect a true difference between two populations) was calculated and sample size was estimated only in the Dublin study.

Eligibility criteria. Eligibility criteria for entry into the study were explicit in all but the first Melbourne study, for which no definition of "high risk" was given.

Allocation of subjects. Randomization both eliminates selection bias and enables the proper use of statistical methods.[12] The investigators in all trials allocated women into electronic fetal monitoring and auscultation groups by means of formal randomization with opaque, sealed envelopes except in Melbourne (see below) and in Copenhagen, where the weeks of participation were randomly allocated. The weekly allocation procedure used by the Danish investigators is subject to selection bias (for example, the decision to induce labor could be affected by the physician's or midwife's desire to assign a patient to an experimental [or control] group).

Because randomization allocates subjects in an unbiased manner, potentially confounding variables tend

*Randomization was attempted but failed in the major study hospital.

to be equally distributed in the experimental and control groups. Nevertheless, it is still useful to assess whether known risk factors and confounders were distributed equally in the study and control groups. This postrandomization assessment was attempted with varying rigor in each of the trials.

Withdrawals. Withdrawals were clearly dealt with only in the Copenhagen and Dublin studies. There were apparently no withdrawals in the Sheffield study, but recognition of the importance of this fact was not apparent in that report. Of the 13,025 women who were eligible for the Dublin trial, 61 (0.5%) were inadvertently not randomized but on review of their hospital records were not found to differ from those included in the study. In the Danish study, 349 women (31%) refused to participate because of a preferred method of intrapartum surveillance (238 of these women had delivery conducted with auscultation, 111 with electronic fetal monitoring).

Retaining the groups as they were originally allocated is essential for the primary analyses, although additional analyses with clearly specified exclusions can be used for supplementary information.[11] Excluding withdrawals, even those beyond the control of the investigators, can vitiate the bias-eliminating effects of randomization.[10] Any other analyses must be considered as supplementary or as hypothesis-generating exercises. Such analyses are often useful but should not be used for hypothesis testing.

Study regimens. Study regimens for both experimental and control groups were well described in each trial. Postrandomization patient compliance was uniformly high. Adherence to the study regimen is crucial but often difficult to assess, unless the investigators make careful efforts either to document deviations from the protocol or to design methods to quantify such deviations. Only the Dublin investigators made extensive efforts to assess adherence to the study regimen, although in both Denver trials as well as the trial in Sheffield the doctors and midwives apparently adhered closely to the regimen. The regimen was seriously breached in both Australian trials. In the first trial one of the eight study physicians withdrew his patients, introducing selection bias. Also, information bias was introduced, since scalp blood measurements were performed only between 9:00 AM and 5:00 PM in that trial. In the second Melbourne trial the cards for allocation were not in sealed envelopes, and the randomization was apparently lost. This led to an increased proportion of primigravid women in the electronic fetal monitoring group, and efforts by the investigators to adjust for this and other unrecognized biases were not successful.

The appropriate use of a technology is a crucial aspect of any study. Although explicit decision pathways based on electronic fetal monitoring results can be constructed, the type and timing of intervention are based ultimately on clinical judgment. This reflects the real world, and one must recognize that these randomized controlled clinical trials measure the effectiveness of management practice (pragmatic trials) rather than the potential efficacy of a procedure in an ideal setting.[12]

"Blinding" of evaluation by pediatricians and statisticians. The conduct of randomized controlled clinical trials is subject to bias when those assessing outcomes are aware of the assignment of a patient to the experimental or control group. Although it was not practical

in these studies to "blind" either patients* or clinicians during labor, it was feasible and desirable to "blind" the assessment of infant outcome. The Denver and Dublin investigators made careful efforts to "blind" the pediatrician who assessed the newborn infants as to allocation of subjects to experimental and control groups, but only the Dublin group prespecified statistical analysis so as to avoid bias. Statisticians were "blinded" as to allocation of newborn infants in the Copenhagen study.

Unambiguous outcomes. When complete blinding is not possible, which was the case in these randomized controlled clinical trials, bias can be decreased by using unambiguous outcomes such as death. Even in this case, however, the attribution of the cause of death could have been biased. A death secondary to fetal distress could, for example, be attributed inappropriately to a cephalopelvic disproportion. Similarly, the increase in the rate of cesarean delivery associated with electronic fetal monitoring that was consistently detected in the trials must be interpreted in light of the fact that the indications for operative delivery are variable and potentially subject to observer bias.

Statistical analysis. This remains a source of confusion in the clinical literature. Clear presentation of the simple distribution of results in both experimental and control groups is essential but is sometimes overlooked. Tests of statistical significance should be presented for major end points, with a clear description of the statistical method. Results should be presented as relative risks or risk differences with appropriate confidence intervals.[13]

Post hoc analysis of hypotheses inspired by looking at subgroup results (data dredging) should not include conventional tests of statistical significance. All the trials of routine electronic fetal monitoring used appropriate

statistics to assess main effects (although only in the Dublin trial were these main effects delineated). Only the Dublin authors calculated confidence intervals and demonstrated an understanding of the distinction between testing of prior hypotheses and the generation of new hypotheses by post hoc analysis.

Complications. While none of the trials were designed explicity to assess the complications of routine electronic fetal monitoring, all investigators measured some of the potentially adverse effects of the procedure, in particular increased rates of cesarean delivery. Only the Dublin trial was large enough, however, to detect differences in rates of less common maternal and neonatal complications previously attributed to electronic fetal monitoring. These investigators detected a statistically significant increase in the occurrence of genital tract infections among women in the electronic fetal monitoring group.

Assessing reports of clinical trials

If one were limited to published data, less could be said about the quality and comparability of the seven trials. To demonstrate this point the published reports of the trials were assessed quantitatively, with use of a previously standardized method for evaluating trials.[11] The method was modified slightly for the assessment of electronic fetal monitoring. A score of >80% is considered good, and occasionally a report is rated >90%. The Dublin trial scored highest for overall quality (86%). Three other trials scored >50%: Sheffield (57%), the second Denver trial (54%), and the Copenhagen study (51%). The other studies scored lower: the first Denver trial scored 45%; the second Melbourne trial, 32%; and the first Melbourne trial, 29%. With addition of unpublished information, each trial might have scored higher. This evaluation emphasizes the importance of adequate reporting of both methods and results. In this instance the published literature leaves the reader with concerns about the quality of all of the initial six trials, especially the first Melbourne trial, which first suggested that intrapartum electronic fetal monitoring may decrease the occurrence of adverse neurological sequelae.

Analysis of the results of the seven trials assessing intrapartum electronic fetal monitoring

None of the initial six trials demonstrated a statistically significant decrease in the rate of perinatal death, stillbirth, neonatal death, 1-minute Apgar score of <7, 1-minute Apgar score of <4, or neonatal intensive care admissions with the use of electronic fetal monitoring (Table II). Only the first Melbourne trial showed a large (although not statistically significant) decrease in neonatal seizures associated with electronic fetal monitoring, as well as a possible decrease in the rate of admission for neonatal intensive care. All of the initial six trials showed an increased rate of cesarean delivery in the electronic fetal monitoring group. The results regarding total operative deliveries were mixed, with increases in the rates of operative deliveries (that is, abdominal and forceps deliveries) in the electronic fetal monitoring group in both Melbourne trials, the second Denver trial, and the Copenhagen study, but decreases associated with electronic fetal monitoring use in the Denver and Sheffield trials.

Pooled analyses. To use trial data more efficiently, results from similar studies can be pooled for analysis.[14] This is particularly useful when trials are too small to detect important effects of an intervention, although one must interpret the results of pooling with caution.[15] In addition to clinical and epidemiologic considerations, pooling is not appropriate in circumstances in which results vary widely. Heterogeneity tests quantitatively measure the extent of outcome variability in trials.[14] In this report we pool the results of the 3928 women in the first six studies.

There was no statistical reason for not pooling data from the six initial studies on Apgar score, neonatal intensive care unit admission, perinatal death, neonatal

E = Electronic fetal monitoring (experimental); A = auscultation (control); V = variance.

*Two experimental groups, with and without fetal scalp blood sampling, were compared to an auscultation group in the second Denver trial.

Table IVB. Pooled data from the six controlled trials

	Pooled relative risk	*95% Confidence interval*	*Test for heterogeneity*
Cesarean deliveries	2.17	1.72-2.73	$x_6^2 = 4.05$ (NS)
Operative vaginal deliveries	1.10	0.95-1.27	$x_6^2 = 11.81$ (NS)
Total operative deliveries	1.42	1.24-1.62	$x_6^2 = 7.40$ (NS)

seizures, and operative deliveries (Tables III and IV). Slight but nonsignificant increases in the electronic fetal monitoring group were found in the number of Apgar scores of <7 and in the perinatal death rate. There were nonsignificant increases in the auscultation group in the number of Apgar scores of <4 and in the number of neonatal seizures. There were significant increases in the electronic fetal monitoring group in the rate of cesarean delivery but a nonsignificant increase in the total rate of operative delivery—both vaginal and abdominal.

Looking only at those randomized controlled clinical trials involving high-risk pregnancies (the Denver trials and the first Melbourne trial), one finds a nonsignificant increase in the electronic fetal monitoring group in the rate of perinatal death (pooled relative risk [RR] =

NICU admissions			*Perinatal deaths*		
E	*A*	*V*	*E*	*A*	*V*
35	28	13.72	2	1	0.75
40	29	9.08	1	1	0.50
45	43	18.19	0	1	0.25
23	29	11.57	2	0	0.50
29	29	12.71	1	0	0.25
59	48	23.65	1	0	0.12
51	49	22.44	0	1	0.25

2.72; 95% confidence interval [CI] = 0.68, 10.88) and infants with Apgar scores of <7 (pooled RR = 1.15; 95% CI = 0.88, 1.50) and nonsignficant decreases in the rates of neonatal intensive care unit admissions, (pooled RR = 0.84; 95% CI = 0.63, 1.12) and neonatal seizures (pooled RR = 0.42; 95% CI = 0.15, 1.20). There were statistically significant increases in the electronic fetal monitoring group in the rate of cesarean deliveries (RR = 2.48; 95% CI = 1.78, 3.16) but essentially no difference in the rate in total operative deliveries in association with high-risk pregnancies (pooled RR = 0.97, 95% CI = 0.79, 1.19).

Finally, in pooling data from the trials in which fetal scalp blood sampling was used to complement electronic monitoring, there were lower but still statistically significant increases in the cesarean delivery rate (pooled RR = 1.81, 95% CI = 1.33, 2.47) and total operative deliveries (pooled RR = 1.47, 95% CI = 1.24, 1.74) in the electronic fetal monitoring group.

The Dublin trial. The Dublin trial of nearly 13,000 subjects demonstrated a decrease in the number of neonatal seizures in the electronic fetal monitoring group. When the data were stratified, this difference in the rate of neonatal seizures in the experimental and control groups was associated with the use of oxytocin in prolonged labor. Six of the 39 infants with seizures—three in each group—showed neurological sequelae at 1 year of age. There were no differences in the rates of perinatal death, stillbirth, or neonatal death. There was no statistically significant difference in the rate of low Apgar score, in the rate of admission to neonatal intensive care, or in other types of neonatal morbidity. Although the increase in cesarean delivery associated with electronic fetal monitoring was not statistically significant, the rate of total operative deliveries was significantly increased in the electronic fetal monitoring group.

Comment

Two important issues are addressed in this report. First, there are specific conclusions that one can draw from the evidence in these seven trials relevant to both clinical practice and further research. Second, while the randomized controlled clinical trial is the most powerful tool available to assess a clinical practice such as electronic fetal monitoring, even this tool has limitations.

The Dublin trial demonstrates excellent design and implementation and illustrates the importance of reviewing even relatively small studies before beginning a major trial. After examining pooled data from the first four trials, the authors of that study found a suggestion for benefit of intrapartum electronic fetal monitoring and fetal acid-base assessment in the reduction of neonatal seizures. A randomized controlled clinical trial was then designed specifically to test this hypothesis. The results of the Dublin trial indicate that the use of electronic fetal monitoring decreases the rate of neonatal seizures in comparable settings, yet the possible limitation of that benefit to selected high-risk pregnancies and the long-term implications of the apparent association of neonatal seizures with the use of intrapartum oxytocin warrant further study. Finally, the trials reviewed here were designed to assess the effectiveness of electronic fetal monitoring in the reduction of specific outcomes. Hence, even if electronic fetal monitoring might better identify an abnormal fetus, intervention during labor may not improve the outcomes of interest.

Despite the excellence of the Dublin trial, one must remain cautious. First, the finding of a decrease of neonatal seizures in the electronic fetal monitoring group is not consistent with the pooled results of the previous trials. Second, even in the Dublin trial the long-term clinical implications of seizures remain unclear. As the authors point out, results of their stratified analyses suggest that the benefits of electronic fetal monitoring are restricted to an association with protracted labor and with women given oxytocin. They state therefore that selective rather than universal use of electronic fetal monitoring may be preferable. Third, one cannot extrapolate from a single trial to other settings in which both the patient population and the clinical practices may vary. The unique circumstances of a clinical trial are likely to result in more careful maternal-fetal surveillance both in the auscultation and electronic fetal monitoring groups than may be practical in other settings. Certainly, an active policy of induction of labor for prolonged pregnancy, the routine use of amniotomy, and the low rate of cesarean delivery (2.3%) in Dublin suggest that the clinical practice there is very different from that in the United States, where the rate of cesarean delivery exceeds 20%. The low prematurity rate in that study population and the policy of exclusion of patients with meconium must also be considered when applying these results to populations in the United States.

It is desirable therefore to interpret cautiously the findings of the Dublin randomized controlled clinical trial in the context of that practice setting. The authors of the second Melbourne trial concluded that each large institution should conduct its own randomized controlled clinical trial to account for variations in clinical practice and patient populations.[8] Although this is not feasible, it would be appropriate to conduct further randomized controlled clinical trials to test the hypothesis that electronic fetal monitoring in conjunction with fetal acid-base assessment reduces the rate of neonatal seizures and their sequelae, particularly among women receiving oxytocin to induce or augment labor.

Randomized controlled clinical trials comparable in size to the Dublin study would also help address important questions of the impact of electronic fetal monitoring on other measures of perinatal morbidity and mortality. To assess the long-term impact of this finding, additional randomized controlled clinical trials will provide a larger cohort of children who had neonatal seizures. The published literature indicates that a neonatal seizure is a serious prognostic finding, yet followup of the 39 Dublin infants with seizures who survived the neonatal period shows no difference in the outcomes of the auscultation and electronic fetal monitoring groups at 1 year of age. This suggests that there may have been a more sensitive diagnostic criterion used in the Dublin trial or that the seizures with adverse prognostic implications are not those affected by early intervention during labor and delivery.

Finally, establishing policy in clinical practice requires not only the determination that a screening procedure is effective but also that the human and monetary costs are acceptable.[16] Moreover, the effectiveness, safety, and acceptability of subsequent interventions must be considered. For example, the evidence reviewed here demonstrates a significant increase in the rates of vaginal and abdominal operative deliveries associated with electronic fetal monitoring, with or without fetal scalp blood sampling. In this light, if electronic fetal monitoring is used in essentially all pregnancies, it will have large, direct financial costs which will increase dramatically if associated with an intervention (for example, cesarean delivery) that may often be unnecessary. Before a rational decision can be made about the routine use of this technology, the value of intrapartum electronic fetal monitoring screening must be assessed in light of the potential benefit of alternative obstetric practices designed to decrease perinatal morbidity and mortality.

First, I wish to acknowledge Dr. H. David Banta for his contributions to this manuscript. In addition, I thank Professors Ian D. Cooke and Mogens Osler and Drs. Adrian Grant, Albert Haverkamp, and Peter Renou for providing background and unpublished data from the clinical trials as well as Dr. Herbert L. Peterson for comments on the manuscript.

A high prevalence of chlamydial cervicitis in postmenopausal women

Tetsuo Nagashima, M.D.
Yokosuka, Japan

One hundred eighty-one healthy women were examined for *Chlamydia trachomatis* of the cervix. The results revealed a high prevalence of chlamydia-positive cases concentrated in postmenopausal ages. We would like to suggest that the primary infections occurred when the subjects were younger and that the organisms have survived for decades. (AM J OBSTET GYNECOL 1987;156:31-2.)

Key words: Chlamydial cervicitis, postmenopausal women, trachomatous conjunctivitis

Many studies on *Chlamydia trachomatis* have been made to date, and it is now known that a large number of asymptomatic infections in women are prevalent worldwide.

Clinical or epidemiologic studies of chlamydial cervical infections, however, focused mainly on sexually active women and thus resulted in a higher positive rate in younger women. Some of them revealed a much higher prevalence among populations sampled by sexually transmitted disease departments, a tendency which apparently seems plausible.

Method

During the period between November 1 and December 10, 1985, a total of 181 healthy women were examined for *C. trachomatis* in the uterine cervix during regular checkups. Their age span was 16 to 65 years, with an average of 38.0 years.

Prostitutes, contacts with men having nongonococcal urethritis and/or other sexually transmitted disease(s), and women who themselves had other sexually transmitted disease(s) (genital herpes, trichomonal vaginitis, gonorrhea, etc.) were excluded from this study, with the exception of those with candida vaginitis.

The number of those excluded was 24, their average age was 25.5 years, and the prevalence of chlamydial cervicitis was 58%.

Examinations were performed with use of the MicroTrak Chlamydia Trachomatis Direct Specimen Test (Syva Company, Palo Alto, CA 94304). Specimens were collected and fixed by me.

Results

Of the 181 cases studied, 10 positive cases were identified, for a 5.5% prevalence rate, which is comparable to the prevalence rate among the general population already reported.

Table I. Prevalence of chlamydial cervicitis in relation to the age of the women examined

Age (yr)	*No. of cases examined*	Chlamydia trachomatis–*positive*	
		n	%
16-19	9	1	11
20-29	26	2	7.7
30-39	50	0	0
40-49	70	1	1.4
50-59	21	5	23.8
60-65	5	1	20
16-65	181	10	5.5

In the age group of women under 40 years, the correlation between positive rate and age corresponded to that of the Swedish population reported on by Weström et al. in 1982.[1]

Contrary to my expectation, however, the age group over 40 years showed a much higher positive rate with seven positive cases, of which six were postmenopausal.

The results are shown in the Table I and Fig. 1.

Each case is described as follows (all women were asymptomatic, and all were Japanese): (1) A 44-year-old premenopausal woman, had a history of corneoconjunctivitis, which was diagnosed 11 years earlier and required considerable time for complete resolution. Her two children were also diagnosed at the same time as having a similar condition. (2) A 50-year-old postmenopausal woman had a history of epidemic conjunctivitis, which was diagnosed 10 years ago and required considerable time for complete resolution. One of her sons was also diagnosed at the same time as having a similar condition. (3) A 57-year-old postmenopausal woman had an uncertain history of trachomatous conjunctivitis at the age of nine or ten years. (4) A 57-year-old postmenopausal woman had no known history of conjunctivitis, but her husband had

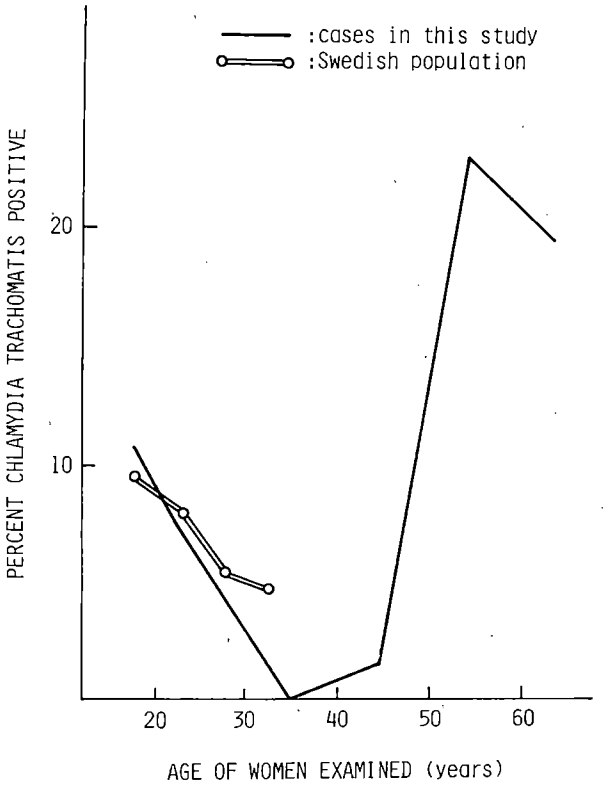

Fig. 1. Results of this study compared to those in the study of the Swedish population by Weström and Mårdh.[1]

history of trachomatous conjunctivitis premaritally. (5) Three other postmenopausal women had no known past or family history of any conjunctivitis.

Comment

Chlamydial cervicitis has long been thought to be most common in young, sexually active women. This study, however, shows a high incidence of asymptomatic chlamydial cervicitis in much older, postmenopausal women.

This finding is significant, since it demonstrates that chlamydial infections can be found in sections of the population in which it was thought such diseases were relatively uncommon.

Before the 1950s, when these subjects were younger, trachomatous conjunctivitis was quite common in Japan, but today it is rarely seen. On the other hand, inclusion conjunctivitis is still widely prevalent in Japan.

It has been established in the literature that the reticulate bodies of chlamydiae may reside intracellularly for long periods of time, protected from host antibodies by their lack of specific antigenicity.[2]

We therefore would like to suggest that the organisms survived within the women examined in this study for long periods of time, perhaps years.

The primary infections of *C. trachomatis* in women could have occurred through mucous membranes, such as in the eyes or elsewhere, with the organisms then surviving for decades before relocating to the uterine cervix through undetermined routes. Alternatively, the organisms could have resided within the cervical epithelia since the initial infections.

Additional studies will shed further light on the high prevalence of chlamydial cervicitis in postmenopausal women.

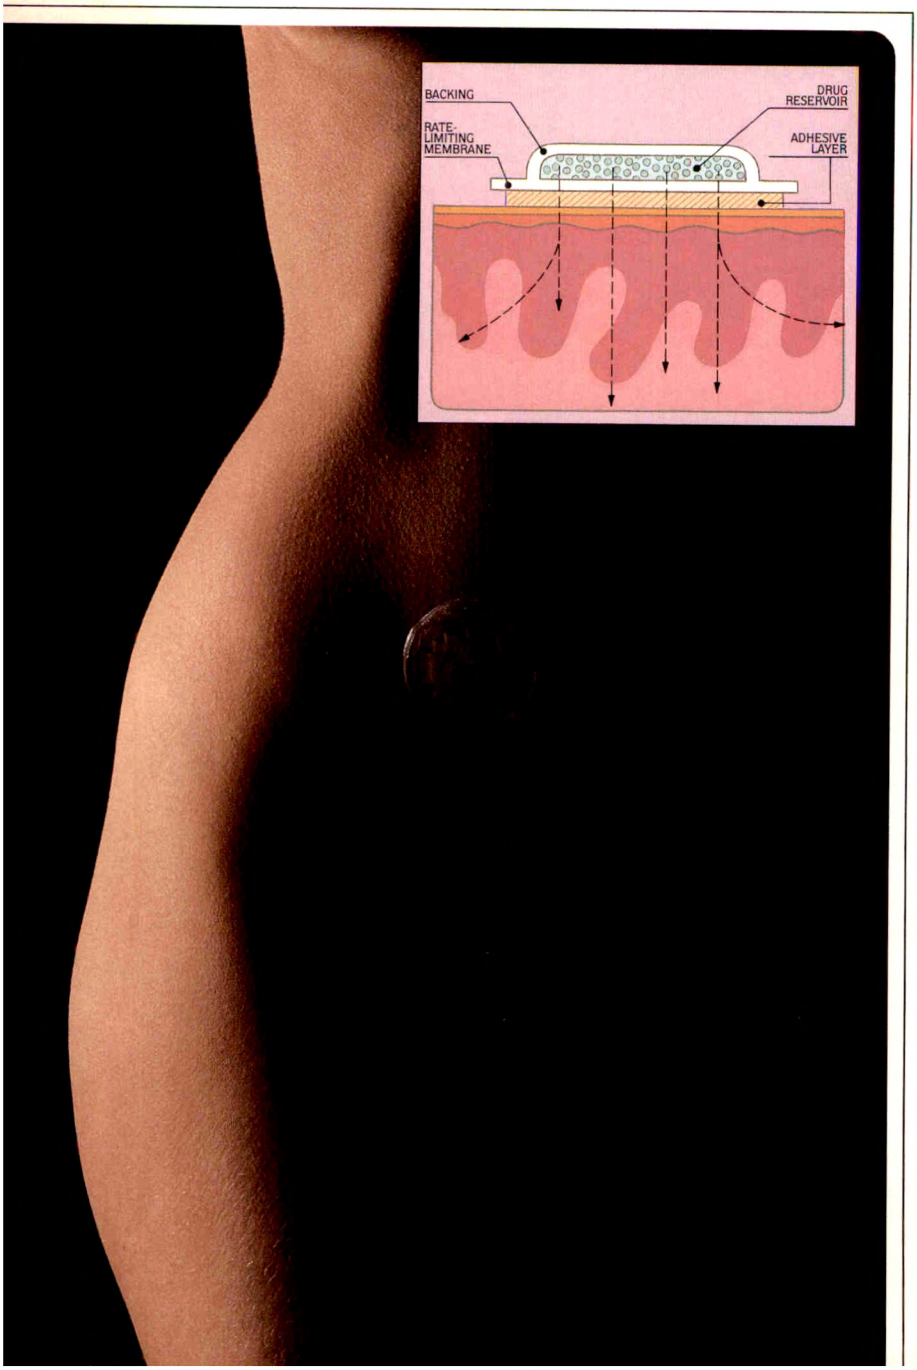
Now

The next generation of estrogen replacement therapy...

transdermal delivery



NEW

ESTRADERM®

estradiol transdermal system

Combines the advantages of transdermal delivery...

A specially designed transdermal delivery system

Providing the natural ovarian estrogen (17-beta estradiol) directly to the bloodstream and target organs; with no first-pass liver metabolism, permits use of extremely low dosage

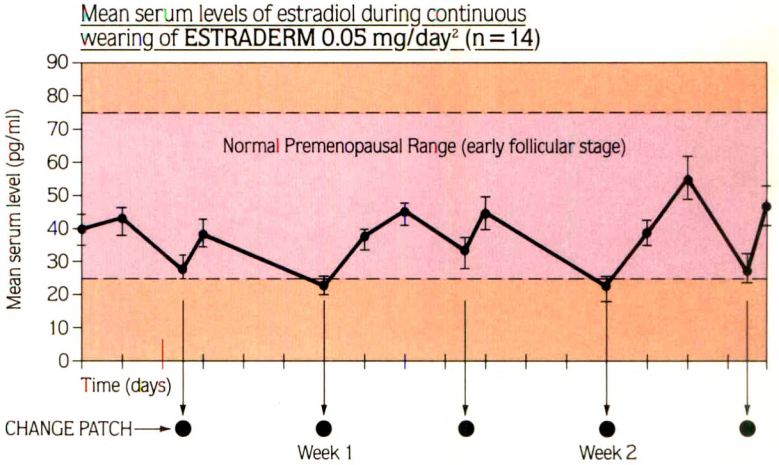
Effectively controls estrogen deficiency symptoms

Steady-state relief of hot flashes, other menopausal symptoms associated with hot flashes, and vaginal discomfort

Well tolerated

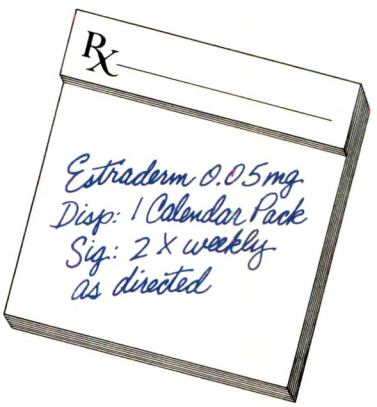
Very low incidence of systemic side effects...few local problems of consequence

Easy to use; transdermal delivery preferred 3:1 by patients over tablets[1]



Usual starting dose: a 0.05-mg system changed twice weekly

C I B A



vith the benefits of
strogen replacement

estores and maintains premenopausal tradiol serum levels

stores estradiol levels to near-normal premenopausal ranges
chieves a physiologic 1:1 ratio of estradiol to estrone

ilable in dose-reminder calendar packs of eight
ches—0.05 mg/0.1 mg

I B A

ping today's women live healthier lives

ESTRADERM®

estradiol transdermal system

Continuous delivery for twice-weekly application.
BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBING INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause, and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Information for Patients

See Patient Package Insert.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG), leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding, spotting, change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

HOW SUPPLIED

Estraderm 0.05 (estradiol transdermal system)—each 10 cm^2 system contains 4 mg of estradiol USP for nominal* delivery of 0.05 mg of estradiol per day

Patient Calendar Pack of 8 Systems — — — — — — — — — — — —NDC 0083-2310-08
Carton of 6 Patient Calendar Packs of 8 Systems — — — — — — — — — —NDC 0083-2310-62

Estraderm 0.1 (estradiol transdermal system)—each 20 cm^2 system contains 8 mg of estradiol USP for nominal* delivery of 0.1 mg of estradiol per day

Patient Calendar Pack of 8 Systems — — — — — — — — — — — —NDC 0083-2320-08
Carton of 6 Patient Calendar Packs of 8 Systems — — — — — — — — — —NDC 0083-2320-62

*In vivo delivery of 0.05 or 0.1 mg of estradiol per day via skin of average permeability (interindividual variation in skin permeability is approximately 20%).

Do not store above 86°F (30°C).
Do not store unpouched. Apply immediately upon removal from the protective pouch.

CAUTION: Federal law prohibits dispensing without prescription.

Alcohol teratogenicity in the human: A detailed assessment of specificity, critical period, and threshold

Claire B. Ernhart, Ph.D., Robert J. Sokol, M.D., Susan Martier, M.S.S.A., Pamela Moron, B.S., Debra Nadler, B.S., Joel W. Ager, Ph.D., and Abraham Wolf, Ph.D.
Cleveland, Ohio, and Detroit, Michigan

Though the occurrence of alcohol-related birth defects is well documented in the human and in animal models, definition of specificity, critical period, and dose-response threshold with a precision adequate for clinical risk assessment and management has been lacking. Data from a cohort of 359 neonates, from a large prospective observational study in which chronic alcohol problems and maternal drinking were assessed during pregnancy and standardized neonatal examinations were blinded for prenatal information, were analyzed with the use of multivariate techniques, with uniform control for confounding by eight factors. Craniofacial abnormalities were found to be definitively related to prenatal alcohol exposure in a dose-response manner ($p < 0.001$); a significant, but less striking, relationship was observed for other anomalies ($p < 0.01$). The critical period for alcohol teratogenicity was confirmed to be around the time of conception. Risk for anatomic abnormalities in the offspring was clearly defined among the 5.6% of infants whose mothers drank more than three ounces of absolute alcohol, that is, more than six drinks, per day. Because of a trend toward an increase in craniofacial abnormalities with increasing embryonic alcohol exposure at lower levels, a clear threshold could not be defined. These are not experimental data and the results should not be overinterpreted. Nevertheless, pending further studies with larger samples, the findings suggest that to completely avoid alcohol-related anatomic abnormalities, advice to discontinue drinking or at least to reduce it to a minimal level before conception is clinically appropriate. (AM J OBSTET GYNECOL 1987;156:33-9.)

Key words: Alcohol-related birth defects, fetal alcohol effects, critical period, neonatal anomalies

That alcohol is a potent teratogen in the human and in several animal models has been well established in a large number of studies published during the last 13 years.[1] Indeed it has been estimated that up to 5% of anatomic congenital anomalies may be attributable to prenatal alcohol exposure.[2] Although the diagnosis of the full fetal alcohol syndrome requires the presence of prenatal and/or postnatal growth retardation, central nervous system involvement, and the presence of characteristic facial dysmorphology,[3] it has been hypothesized that lesser effects, including isolated congenital defects, may be associated with lower, less frequent and/or differently timed doses of alcohol.

Defining alcohol teratogenicity in the human with a precision desirable for offering patients rational advice and for clinical risk assessment and management has been difficult. First, the drinking of alcoholic beverages is a complex human behavior; it is difficult to accurately ascertain historically and difficult to represent quantitatively.[1, 3] Second, the pattern of alcohol-related birth defects in individuals is not invariant. The list of features observed is lengthy[4] and no single feature is noted in every case. Few reports describe the frequency of each. One exception is an early article by Hanson et al.,[5] which included a tabulation of the occurrence of nine physical anomalies recorded for 41 children with fetal alcohol syndrome. The most frequently noted feature, short palpebral fissures, was observed in 92% of the children. No other feature was reported for more than 65% of the sample.

Our research group has been studying alcohol-related risks in human pregnancy for several years. In a previous report,[6] we described a neonatal examination for anomalies, which was based on the descriptions of fetal alcohol syndrome by Hanson et al.[5] and others. A tally of detected anatomic abnormalities was found to be related significantly to maternal alcohol abuse, as measured by the Michigan Alcoholism Screening Test

(MAST).[7] In the MAST-positive group a dose-response relationship between first-trimester alcohol exposure and the tally was obtained. While maternal alcohol use was related to neonatal size (another of the reported sequelae of fetal alcohol exposure), this effect was attenuated with control of parental size measures. Neonatal behavior scores were unrelated to the MAST classification and to maternal alcohol use. Thus the anomalies tally appeared to be more sensitive to prenatal alcohol exposure than either infant size or behavioral measures.

To define alcohol teratogenicity in the human as precisely as possible, the present report extends our previous findings by attempting to answer three questions concerning the association of fetal alcohol exposure and neonatal anomalies. First, are craniofacial anomalies more specifically related to alcohol exposure early in gestation than other anomalies? Second, can a critical period for alcohol-related dysmorphology be identified? Third, can a threshold for alcohol-related teratogenicity be discerned?

Background and rationale

Specificity of craniofacial anomalies. Two issues bear on the decision to differentiate craniofacial anomalies from other anomalies in the analyses to be presented. First, an analysis demonstrating a strong and rather specific alcohol exposure relationship with craniofacial features would strengthen the inference that the abnormalities observed are alcohol-related. Second, given that individuals differ in their vulnerability to alcohol exposure, the focus on craniofacial anomalies might provide us with a neonatal indicator of later developmental deficit.

The possibility that abnormalities apparently related to fetal alcohol exposure might be attributable to confounding conditions, such as smoking, use of other drugs, and poor nutrition, is difficult to rule out in studies in humans.[1, 2] Given the limitations of the assessment of such conditions and the interrelatedness of such variables in epidemiologic studies, control through statistical methods often underadjusts. The attribution of effect to alcohol exposure, however, would be enhanced given that the effect is stronger for those anomalies that are most distinctive and which have been specifically linked to fetal alcohol exposure, i.e., the craniofacial anomalies.

Craniofacial anomalies observed in the neonatal period may provide a powerful indicator of later functioning level, because of a possible association with functional deficits of the sensory organs or with abnormal growth of the brain.[8, 9] We plan to examine this important perinatal developmental issue, with medicological implications, in a later study of this cohort of children.

The Anomalies Tally included both craniofacial anomalies and various cardiac, muscular, and skeletal features described in various reports of fetal alcohol syndrome. The specific hypothesis in the current study was that the effect of alcohol exposure would be more decisive in the group of craniofacial anomalies than in the group of other anomalies.

Critical period. The timing of prenatal exposure to alcohol would be expected to be a major determinant of the adverse effects observed. Thus alcohol-related intrauterine growth retardation[10] and disruption of the normal appearance of amniotic fluid phospholipids[11] have been shown to be related to continued maternal drinking in the third trimester; neither fetal alcohol effect was observed in pregnancies in which the mother became abstinent before that period, with clear implications for prevention.[1]

An issue of considerable clinical as well as theoretical importance concerns the specific time during pregnancy of greatest vulnerability to alcohol teratogenicity. It is generally recognized that the first trimester, in particular, the period from 4 to 10 weeks' gestation (that is, from 2 to 8 conceptual weeks, which is the time of embryogenesis), is most critical for the induction of anatomic abnormalities. It was for this reason that our initial analyses assessed the effects of first-trimester exposure for this outcome measure.[6] However, in our previous study, data concerning early pregnancy exposure were based on maternal drinking data from a mean of approximately 12 weeks' gestation. We now contrast this time of exposure with an index heavily weighted with second-trimester exposure and, most importantly, an index that is an estimate of embryonic alcohol use.

Threshold. In our previous report of the relationship of anomalies and alcohol use among women with positive MAST results, an augmented effect for the women reporting the highest alcohol use was noted.[6] In the present report, we attempt to identify a threshold of effect for alcohol-related neonatal anomalies. Identification of a threshold, if present, for this apparently very sensitive fetal alcohol effect would be most useful clinically in counseling patients concerning alcohol risk to their offspring.

Methods

A description of the sample and the methods of collecting the data has been reported previously[12] and a summary is presented here. This study was approved by the human investigation committee of the institution.

Sample. The infants in this study were the offspring of disadvantaged urban women who were screened at their first antenatal visit for chronic alcohol problems. The instrument used was the MAST.[7] This is a well-studied, widely used, 25-question instrument, focusing on alcohol-related psychosocial disruption, for the de-

tection of chronic alcohol problems, that is, alcohol abuse and alcohol dependence. Evidence of the validity of the MAST for the present study comes from research describing an earlier sample of 2913 women from the same population.[12] In this report, MAST-positive pregnant women were found to be 8.3 times more likely to have reported drinking ≥1 ounce of absolute alcohol per day, 19 times more likely to have reported drinking ≥2 ounces of absolute alcohol per day, and 17.5 times more likely to have reported drinking ≥3 ounces of absolute alcohol per day than women with negative MAST results. The score can range from 0 to 53, with a score of ≥5 considered positive.

The MAST was administered to all gravid women presenting for antenatal care in the clinic setting of a hospital that serves primarily disadvantaged patients. (About 80% to 90% of hospital patients are in Social Classes IV and V, Hollingshead Two Factor Index. Among those using the clinic this is close to 100%.) From this population all MAST-positive women and matched control subjects (MAST negative) were entered in a study of the use of alcohol in pregnancy extending over a period of several years.[12] The matching variables were race, smoking, parity, date of recruitment, drug abuse, prepregnancy weight, and weeks' gestation at registration. From this study of matched MAST-positive and MAST-negative gravid women studied through pregnancy, 543 deliveries occurred within a specified 15-month period. These mother-infant pairs were reviewed for inclusion in a cohort to be followed up through the child's preschool years for the evaluation of alcohol-related birth defects. Infants were excluded from the prospective study as follows: 87 for health-related reasons (gestation <37 weeks, indications for neonatal intensive care, maternal psychosis, and maternal narcotics use), 47 because of parental refusal, 16 because of primary language other than English, 14 because they were missed by the research staff (weekend delivery and discharge), 10 because of plans to move from the area, and 10 because of adoption. The cohort included 359 mother-infant pairs. Of these, 113 were black and 246 were white. In order to avoid the exclusion of yoked cases, one-to-one matching was not retained for the neonatal or prospective study.

Examination. Each neonate was examined by a trained research nurse who was blinded to the individual histories of prenatal alcohol exposure. A listing of anomalies observed in one or more of the 359 children of the study is provided in Table I. The tallies ranged from 0 to 11, with 26 (7.2%) of the 359 neonates presenting no tallied item. Considered individually, most items of the Anomalies Tally are neither very unusual nor very worrisome. The rationale behind the development of the Anomalies Tally is that, as the number of these increases, the results of the examination become more characteristic of the pattern of dysmorphology identified with fetal alcohol syndrome.

The items of the Anomalies Tally observed among the children of the study were divided into those of the

Table II. The relation of first-trimester alcohol exposure to craniofacial and other anomalies among infants of MAST-positive women

Anomalies index	*Alcohol exposure index*	*Covariate (% of variance)*	*Increment (% of variance)*	*F*	*p*
Craniofacial	Absolute alcohol per day, first trimester	12.0	3.6	6.88	0.01
	Proportion/drinking days	12.0	4.9	9.52	0.002
Other	Absolute alcohol per day, first trimester	8.3	0.5	0.94	0.33
	Proportion/drinking days	8.3	0.8	1.38	0.24

The variance for the missing data variables is not included in either the covariate or exposure-increment variance.

craniofacial area and those of a more general nature. This division and the frequency of each item in the MAST-positive and MAST-negative groups are also indicated in Table I. Craniofacial items not noted in the cohort were ptosis, cleft palate, and cleft lip. Among the other anomalies listed for examination, inguinal hernia was not recorded for any infant in the study.

Indices of alcohol exposure. The first indicator suggesting fetal alcohol exposure was the initial selection criterion, positive or negative MAST classification. While some MAST-positive women described themselves as being abstinent during pregnancy, MAST-positive women averaged moderately high levels of alcohol consumption.[12] Furthermore, as previously reported,[6] all women in the highest category of first-trimester alcohol use were MAST positive. This association of the MAST classification and alcohol use further enhances the validity of the MAST for use with pregnant women.

In addition to the administration of the MAST at the first antenatal visit, carefully structured interviews[13] were used at each antenatal visit to elicit a recall of alcohol use on a day-by-day basis for beer, wine, and liquor. The major indices of alcohol use were based on ounces of absolute alcohol per day. The median and modal point in pregnancy for the first interview was 19 weeks and the index computed for the data of this visit is designated as "absolute alcohol per day, second trimester," in the analyses that follow.

Of the 359 participants, 139 had enrolled before the end of the first trimester; all available first-trimester sampled days were used to compute "first-trimester absolute alcohol per day" for these cases. The availability of first-trimester data was not related significantly to the respective outcome measures. In the regression analyses that follow, the lack of data for the remaining cases was handled through the use of a missing data variable.[14] The use of the missing data variable in these analyses served both to maintain the statistical power of the analyses and to provide a test of any bias that might be introduced by the sampling limitations. The tests for bias were negative in each analysis; that is, the respective indices for neonatal anomalies did not differ as a function of whether or not the mother enrolled for care in the first trimester.

The third index of alcohol exposure is designated as "embryonic absolute alcohol per day." A note of explanation is in order. Neither measures of alcohol use at or about the time of conception nor measures of prepregnancy drinking were included in the original protocol. Since the period shortly after conception is the period of embryogenesis and possibly the period of greatest risk for alcohol-related dysmorphology, we sought a method of using the available data (MAST score and measures of alcohol use during pregnancy) to provide estimates for each individual of alcohol consumption at that period.

The method by which this index was developed has been reported previously.[15] In brief, in a separate sample of 57 intensively studied pregnant women in a different city, at a median gestational duration of 19 weeks, women were interviewed with respect to their alcohol intake during the previous 2 weeks. The interview protocol, including the administration of the MAST, followed closely the carefully structured and nonthreatening techniques used originally in the present study.[13] (The structure of the interview asks for recall of amounts and kinds of beverage by day of the week. Reference to relevant social and entertainment activities is used to aid recall by days.) The women were then questioned in a similar manner about their usual prepregnancy drinking and about their drinking at the time at which they thought they conceived. In this interview the prepregnancy and current drinking estimates provided structure for the questions regarding drinking about the time of conception.

Multiple regression analysis of the data of these 57 women, with MAST score and current drinking (absolute alcohol per day) used as independent variables and embryonic drinking used as the dependent variable, yielded the following equation: embryonic absolute alcohol per day = (0.12 × MAST score) + (0.67 × current absolute alcohol per day) + 0.08. (R^2 = 37.1%.) This equation was executed for each pregnancy in the current sample. The resulting estimate was used as an index of embryonic alcohol exposure.

One additional index used in the specificity analyses was proportion of drinking days in the first trimester.

Table III. The relationship of congenital anomalies to absolute alcohol per day in three periods of exposure

Period of exposure	*Anomalies*	*Covariate (% of variance)*	*Increment (% of variance)*	*F*	*p*
Second trimester	Craniofacial	8.5	0.7	2.64	0.11
	Other	8.7	0.4	1.51	0.22
First trimester*	Craniofacial	8.5	1.3	4.79	0.03
	Other	8.7	0.7	2.48	0.12
Embryonic	Craniofacial	8.5	3.4	13.46	0.000
	Other	8.7	2.4	9.29	0.002

*A missing data variable was used in first-trimester analyses. The missing data variance is not included in either the covariate or the exposure-increment variance.

This index of persistence or regularity of maternal drinking was computed as the ratio of days on which drinking occurred to the number of days covered in the interviews.

Methods of data analysis. Initial analyses used *t* tests to contrast MAST-positive and MAST-negative groups. These provide only a preliminary indication of the relations involved, since they did not control for confounding variables. Eight covariates were selected a priori as possible confounders. These were maternal age, race, parity, nutrition, cigarette smoking, the use of marijuana, and the use of other illicit drugs during pregnancy. Demographic data were obtained at the first antenatal visit. Other data (aside from infant sex) were collected in interviews during the course of pregnancy. We have previously reported the association of MAST classification and nutritional measures.[12] We have also previously noted an association of race, maternal age, and parity and the use of illicit drugs with a full tally of anomalies (both craniofacial and other).[6] In order to maintain consistency between analyses, we did not eliminate the nonsignificant covariates in the analyses but used the full set in each statistical model.

The statistical method used for all but the initial analyses was incremental multiple regression with the independent variable under test entered after the full set of covariates.[14] Because the absolute alcohol per day indices were positively skewed, logarithmic transformations were used.

Because of multiple comparisons made in the study, $0.05 < p < 0.01$ was considered borderline and $p < 0.01$, significant.

Results

Specificity. Table I includes *t* tests substantiating significant differences between the MAST-positive and MAST-negative groups for the tabulations of craniofacial and other anomalies. These were further tested in regression analyses with MAST as the independent variable, control of the covariates, and the two tallies as dependent variables. For the craniofacial tally the initial variance of the model (associated with covariates) was 8.5% and the variance increment associated with the MAST classification was 2.6% ($p = 0.002$). For the other anomalies, the initial variance was 8.7% and the variance increment for the MAST was 1.0% ($p = 0.06$). For both tallies the covariate contributing most strongly to the models was race.

Because a much wider range of alcohol use was reported by MAST-positive women, further tests of the specificity of the craniofacial anomalies were made separately for the infants of MAST-positive and MAST-negative women. As shown in Table II, among infants from MAST-positive pregnancies, the count of craniofacial anomalies was related significantly both to the first-trimester absolute alcohol per day and to the proportion of drinking days; corresponding analyses for members of the MAST-negative group failed to reach statistical significance. In both groups the variance in other anomalies accounted for by the first-trimester alcohol indices was small and nonsignificant.

Critical period. Data for the entire sample ($n = 359$) were used for comparisons of the three periods of exposure for each of the two measures of congenital anomalies. As shown in Table III, neither of the counts of congenital anomalies was related significantly to absolute alcohol per day, second trimester, and only the count of craniofacial anomalies was related significantly to absolute alcohol per day, first trimester. Embryonic absolute alcohol per day explained considerably more variance in both the craniofacial and the other anomalies than either late first-trimester or second-trimester absolute alcohol per day indices.

Threshold. The relationship of each group of anomalies, residualized for the eight covariates, to the embryonic alcohol index is shown in Fig. 1. The craniofacial anomalies were related in a consistent dose-response manner to maternal drinking in the period of embryonic development. In spite of one slightly deviant point, the plot for other anomalies was generally consistent with the expected dose-response pattern. The graphed data suggest the possibility of a nonlinear fit, that is, that the effect was due primarily to the peak incidence at absolute alcohol per day >3.0. This pos-

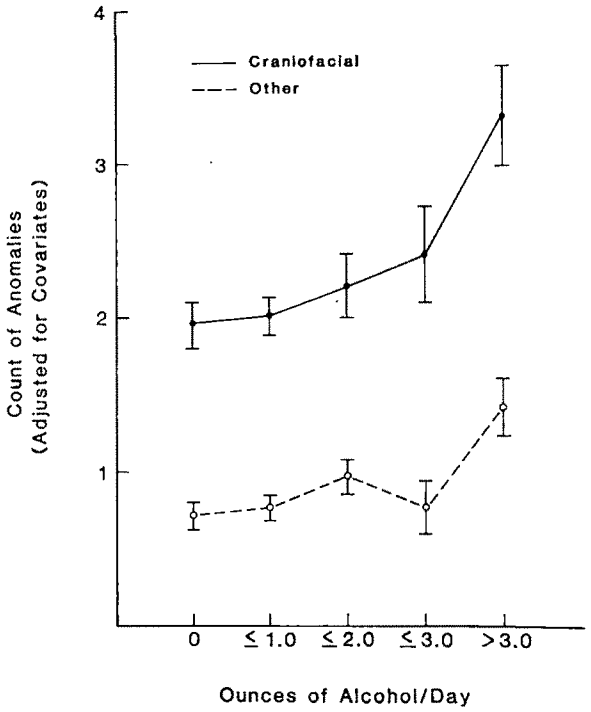

Fig. 1. Means (+SE) of craniofacial and other anomalies, both residualized for eight covariates, as a function of embryonic absolute alcohol per day in ounces. For absolute alcohol per day = 0, n = 95; for <1.0, n = 161; for <2.0, n = 60; for <3.0, n = 23; and for >3.0, n = 20. F and p values are shown in Table III.

sibility was tested in two ways. The first, a polynomial analysis with inclusion of a quadratic term, was not significant for either anomalies measure; the hypothesis of a nonlinear relationship was not supported. The possibility of a threshold of effect was also explored through truncation of the 20 cases (5.6% of the sample) with absolute alcohol per day >3.0. Under truncation, the effect sizes for the craniofacial and other anomalies were reduced to 1.6% and 0.9%, respectively. For the craniofacial anomalies, this remaining incremental variance was of borderline statistical significance (p = 0.017).

Comment

The key findings of this study are that anatomic abnormalities detectable in the neonate, particularly of the craniofacial area, are related in a clear dose-response manner to prenatal alcohol exposure and that, as would be expected embryologically, the critical period is in the early first trimester, that is, the embryonic period. Though there has been convincing evidence for a dose-response relationship between prenatal alcohol exposure and a range of adverse outcomes in animal models[1] and evidence in the human for a dose-response relationship to risk for small for gestational age birth, to the best of our knowledge, the current findings are the first to define a dose-response relationship between embryonic exposure to alcohol and a specific set of anatomic congenital abnormalities in the human.

These findings must not be overinterpreted. These are not experimental data. Although neonatal examinations were blinded for all prenatal information, including maternal drinking history,[12] and we have been unable to detect bias in these examinations, despite extensive analyses, there is still a possibility of confounding in observational data. Statistical control, often incomplete, here for eight covariates, may or may not have been entirely adequate. It is possible, for example, that the nutrition measures (24-hour recall for Recommended Dietary Allowances in five food categories) may not have been sufficiently sensitive to alcohol-related nutritional deficits and that such deficits are the immediate antecedents of the anomalies observed. Data consistent with this interpretation would not eliminate alcohol in the chain of causation, but they would describe the causal pathway more specifically than is the case with the present data set. Such considerations cannot be dismissed completely in epidemiologic analyses such as this. Nevertheless, aside from a few very rare conditions, such as fetal hydantoin syndrome, the pattern of anomalies associated with fetal alcohol syndrome appears from the current analysis, as well as clinically, to be reasonably specific to the infant exposed to alcohol prenatally.

An additional caveat relates to the finding that even with statistical control of covariates, the association of MAST classification and craniofacial abnormalities remained strong and highly significant. The MAST measures chronic alcohol-related problems, so this finding is not inconsistent with the inference that maternal physiologic change secondary to alcohol dependence-abuse might contribute to abnormal infant outcome, as suggested by Majewski and Goecke.[4] Alternatively, we have previously shown that drinking near the time of conception, the period of maximal vulnerability for anatomic defects, is nearly as heavy as that in the nonpregnant state.[15] Because of the strong correlation between MAST and absolute alcohol per day, whether it is the alcohol, the alcoholism, or both, so to speak, cannot be determined from these data. Results from animal studies, however, suggest that the major effect results from direct exposure of the embryo to alcohol.

Two of the aims of the study, the greater specification of craniofacial anomalies and the identification of a critical period for exposure, are defined clearly in the findings detailed in this report. The further use of the data in a search for a threshold of effect was less definitive. We are very confident in concluding that the consumption of more than 3 ounces of absolute alcohol per day, that is, six cans of beer, glasses of wine, or

mixed drinks per day, at or about the time of conception greatly increases the risk for alcohol teratogenicity. A "no effect zone" often seen with teratogens might be expected. Indeed, some studies, for instance, that of Lumley et al.,[16] have not detected an alcohol effect at low levels of intake. However, in the current sample, truncation to retain only those subjects consuming less alcohol reduced, but did not wholly eliminate, this effect. This reduction in the effect and the curvilinear trend presented in Fig. 1 suggest that a threshold level might be observed with a larger database, but the trend toward an effect at lower doses suggests a clinical implication. Prudence supports the recommendation that to completely avoid alcohol-related anatomic abnormalities, women who are planning pregnancy should avoid alcohol consumption or, at least, reduce their consumption to a minimal level.

We are grateful for the assistance provided by Sheldon Miller, M.D., Mary J. Kennard, R.N., C.P.N.P., and Nancy Golden, M.D.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Abruptio placentae: Clinical management in nonacute cases

John S. Sholl, M.D.
Evanston, Illinois

One hundred thirty cases of clinically diagnosed abruptio placentae encompassing the wide range of acuity were grouped by gestational age at delivery into previable, preterm, and term divisions for comparison of demographic data, presenting symptoms, delay to delivery, mode of delivery, and delivery indications. Attention was focused on the preterm group of patients to assess the implications of presenting symptoms, the usefulness of ultrasonography, and the safety and efficacy of tocolysis. Cigarette smoking and a previous poor obstetric history were found to be more frequent in the preterm compared to the term abruptio placentae. Ultrasonic visualization of a clot was successful in 25% of the preterm patients but otherwise appeared to have little or no impact on course or management. Tocolysis for the preterm patients appeared to be beneficial in prolonging gestation and did not increase the likelihood of cesarean delivery, hemorrhage, or fetal distress. The cumulative rates of delivery following admission were compared with and without tocolysis, with and without sonographic visualization of a clot, and overall as a function of gestational age at initial hospitalization. Perinatal mortality was 17%. Inpatient management with frequent fetal heart rate monitoring, tocolysis if indicated, and timely use of cesarean delivery are advocated to promote prolongation of the pregnancy and minimized perinatal mortality. (AM J OBSTET GYNECOL 1987;156:40-51.)

Key words: Abruptio placentae, ultrasonography, tocolysis

Bleeding in the third trimester of pregnancy has been reported to occur in approximately 4% of pregnancies. Among these episodes about 20% can be attributed to placenta previa and 30% to definitive abruptio placentae.[1] Thus about half of the bleeding episodes in pregnancy remain ill-defined as small or "marginal" placental separations (sometimes associated with labor), as local birth canal lesions, or as bleeding with no determinable etiology. Heretofore, attention has been focused mostly on abruptio placentae of significant consequence, that is, grades 2 or 3 in the classification system first proposed by Page et al.[2] (Table I), with maternal hemodynamic instability, coagulopathy, fetal distress or death,[3-6] or exclusively toward cases of abruptio placentae that have resulted in fetal death.[7] A number of authors have concentrated on the risk factors associated with such major cases, which have included hypertension, multiparity, cigarette smoking, previous abruptio placentae, and occasionally trauma.[7-9] With these cases of acute abruptio placentae the need for rapid diagnosis and treatment and the significant impact of cesarean delivery in reducing perinatal mortality have been emphasized.[4, 5, 10, 11]

"Marginal sinus separation," "chronic abruption," or "limited abruption" are nonstandardized terms to categorize bleeding that has a more prolonged and/or perhaps transiently noncatastrophic course when placenta previa, birth canal injury, and major abruptio placentae, that is, grades 2 or 3, are not ultimately diagnosed. The natural history, evolution, management guidelines, and clinical course of this latter category of abruptio placentae appear sparsely presented or discussed in the medical literature, although these episodes represent the majority of encounters for most obstetricians.

In this nonacute category of abruptio placentae the diagnosis is often tenuous and rests on the subjective clinical impression that the bleeding results from premature, nonphysiologic separation of the placenta. The histologic examination is often nonconfirmatory after birth, particularly in the term laboring patient, after the complete and normal physiologic separation of the placenta has taken place. Histologic features are logically not present if the blood does not coagulate under the placenta or membranes but instead egresses through the cervix.

Without much descriptive literature of the nonacute abruptio placentae, numerous questions arise as to the appropriate management and ultimate outcome of this circumstance. Thus the particular objectives of this study were to examine such questions as whether there are hazards or benefits of tocolysis, what is the likelihood of a future extensive placental separation with acute distress or fetal loss with conservative management, and under what circumstances and for how long pregnancies may be safely maintained. In recent years ultrasound examinations have been reported in small

Table I. Classification of abruptio placentae according to maternal and fetal signs

*Grade**	*Concealed hemorrhage*	*Uterine tenderness*	*Maternal hypotension*	*Coagulopathy*	*Fetal distress*
0	No	No	No	No	No
1	No	No	No	No	No
2	Yes	Yes	No	Rare	Yes
3	Yes	Yes	Yes	Often	Death

*Grade 0 is a retrospective diagnosis from inspection of the placenta. Grade 1 includes "marginal sinus" separation or other limited processes of abruptio placentae. Grades 2 and 3 imply significant hemorrhage requiring immediate therapy with the possibility of maternal complications.

series showing abruptio placentae findings.[12-14] Thus an additional issue is with what frequency ultrasound examination is capable of showing the abruptio placentae process and whether such clarification of the diagnosis offers any useful clinical parameters toward management of the patient.

The current report originates from the Evanston Hospital—a regional perinatal center serving the community of Evanston and surrounding north shore Chicago suburbs to the Wisconsin border. With use of computerized delivery data citing abruptio placentae as a delivery complication, cases were reviewed and clinical data tabulated to report on the broad spectrum of clinically diagnosed cases of abruptio placentae over 33 consecutive months.

Material and methods

Since July 1, 1983, delivery data at Evanston Hospital (labor delivery summary) have been computerized for the purpose of statistical analysis and review. With use of the clinical diagnosis of abruptio placentae as reported by the attending physician following delivery, patients were identified, their hospital charts reviewed, and clinical data abstracted into a study record encompassing July 1, 1983, to March 31, 1986. Several additional case records were obtained from the medical records department by search of the abruptio placentae ICD-9 code wherein the diagnosis of abruptio placentae was made at an antepartum hospitalization (without delivery), but without abruptio placentae being diagnosed at the subsequent hospitalization for delivery. One hundred thirty study records were accessed, limited to delivery between 20 to 42 weeks of estimated gestational age (best clinical estimate based on either last menses or ultrasound examinations), although several of the youngest gestational age cases (that is, <25 weeks) were managed as late abortions with nonviable severely premature fetuses. The abstracted data included gestational age at admission, presenting symptoms, gravity, parity, initial hemoglobin, hematocrit, platelet count, prothrombin time, partial thromboplastin time, low hemoglobin, low hematocrit, transfusions, tocolytic use, duration of use, clinical course, delivery indications, estimated gestational age at delivery, delivery type, fetal weight, Apgar scores, umbilical cord blood gases if obtained, and statements in the delivery or operative summary which reported findings such as marginally attached clots, excessive bleeding, definitive retroplacental clots. If ultrasound examination was done by the attending or house staff in the labor and delivery suite, the reported findings were entered for the record. Finally, the findings of ultrasound examinations performed by the obstetric ultrasonography laboratory during the presumptive course of the abruptio placentae were retrieved and entered on the study record. In anticipation of this report, and with the clinical suspicion of abruptio placentae, particular attention was directed to any abruptio placentae findings on ultrasound examination. The 130 case study records were thereafter entered in a computer file, enabling sorting and tabulation of the data. Admitting symptoms (one or more) were grouped with use of the admitting history terminology and physical descriptions: bleeding, spotting, chronic spotting (>4 weeks' duration), cramping, contractions, spontaneous rupture of membranes, hypertension or preeclampsia, back pain, or active labor. Delivery indications (one or more) were similarily categorized among the following from the clinical record: hemorrhage, active labor, cervical dilation, fetal distress (severe variable decelerations, late decelerations), fetal maturity, other. Surgical findings in the delivery or operation record were grouped as follows: old clots (judged to be well organized, fixed, or with friable quality), new clots, excessive bleeding, marginally attached clots, negative (no findings of abruptio placentae), vacant (no statements in the record), or simply abruptio placentae.

In reviewing the accumulated data regarding the objectives of the study, natural divisions became evident allowing placement of patients into three groups for analysis and discussion—those delivering severely prematurely at gestational week 20 to week 25 plus 3 days in whom fetal or neonatal death occurred without much effort or success in prolonging pregnancy (previable group); a middle group delivering between week 25 plus 6 days to week 36 plus 6 days of gestation (preterm

group); and last, the group delivering at a mature gestational age of >37 weeks for whom, in the face of suspected abruptio placentae or with the abruptio placentae process occurring during the course of active labor, maintenance of the pregnancy was not an issue and rarely undertaken. The middle group, those whose pregnancies were often able to be maintained with conservative management and/or tocolytic use, became the focal point of the report and of principal concern regarding the premature infant in the clinical management of nonacute abruptio placentae. The statistical methods used included χ^2 analysis with either the Yates correction or Fischer's exact test for small sample sizes and one application of the Kruskal-Wallis one-way analysis of variance.

Results

The mature group at delivery accounted for 50 mothers and 50 infants delivered at week 37 to week 42 plus 1 day of gestation. The demographic data are presented in Table II. The presenting symptoms are shown in Table III, which indicates a preponderance of patients presenting with spontaneous rupture of membranes and a distinct incidence of back pain occurring with any other symptoms. Within these term deliveries with abruptio placentae were three patients who had been previously admitted to the hospital with bleeding and a consequent clinical diagnosis of marginal sinus bleeding or limited abruptio placentae. These admissions were 79, 57, and 36 days before delivery. All three had been examined by ultrasound dur-

ing the previous admission, with negative findings for abruptio placentae. At delivery the placental examination was negative for evidence of the old abruptio placentae in two patients; however, old clots adherent to the placenta were evident in the 36-day patient. The remaining 47 patients did not have ultrasound examinations during the course of the labor and delivery, and 46 of the 47 were delivered within 0 to 1 calendar day of admission as expected. The mode of delivery is presented in Table IV.

Among the 16 cesarean sections, 14 were performed with a delivery indication of hemorrhage or fetal distress. The remaining two included one repeat cesarean section in labor and one primary case for which the diagnosis of abruptio placentae was made at the time of operation. The initial admitting diagnosis was abruptio placentae in nine cases. In seven of these delivery was expeditiously performed by cesarean section—one vaginally after measuring 7 cm at admission (3317 gm; Apgar scores, 8 and 9) and the other was the one with an abruptio placentae diagnosis 79 days earlier (3629 gm; Apgar scores, 8 and 9) with no abruptio placentae findings at delivery.

Neonatal outcomes of the term abruptio placentae patients were 48 living surviving infants with a weight range of 1745 to 4423 gm. These 48 infants had 5-minute Apgar scores of 8 to 10. Two infants were born with Apgar scores of 0 and 0, and both died. Baby C (3050 gm), who died on day 1 of life, was known to have a large diaphragmatic hernia antenatally with an 80% abruptio placentae occurring in the hospital the night before a planned repeat cesarean delivery. Baby W (3310 gm) was delivered by low forceps with rapid bright red bleeding occurring during the late second stage of labor. This severely asphyxiated infant lived 13 days. Operative report descriptions of the placenta and delivery course included 11 marginally attached clots, 30 cases of abruptio placentae, 17 instances of excessive bleeding, seven new clots, two old clots, and four negative or vacant statements.

Review of the predelivery and postdelivery hemoglobin/hematocrit values and platelet and clotting assays in the mature group showed nominal blood loss in the great majority with many patients lacking postdelivery values. Three patients received 1 to 2 U transfusions. Patient C, whose infant was described above and who had the massive abruptio placentae in hospital, received 4 U of packed red blood cells. Additionally, this was the only patient among 15 assayed who had clotting dysfunction. Platelet counts were obtained in 20 of the 50 term abruptio placentae patients and were $<150{,}000/mm^3$ in only four instances. The average hemoglobin drop of these four was 2.6 gm/100 ml and, given the wide variation, was not statistically different from the mean 2.1 gm/100 ml drop in hemoglobin of 12 other patients (with available data) whose platelet counts were $>150{,}000/mm^3$.

At the previable gestational ages of 20 weeks to 25 weeks plus 3 days, eight cases were segregated based on the gestational age and outcome similarities. Their demographic data are also presented in Table I. Five patients reported chronic spotting (at least 4 weeks) as a presenting symptom with cramping or contractions at admission. Two with this chronic spotting and a third patient who complained of back pain, sustained spontaneous rupture of membranes leading to admission. The seventh patient presented with severe preeclampsia at gestational week 23 plus 6 days. The eighth patient in the group presented with spotting and active preterm labor at 10 cm dilation. The initial diagnosis was abruptio placentae in four of the eight, with the one preeclampsia case and three additional cases diagnosed as having preterm labor completing the group. The three patients in active preterm labor were delivered vaginally, as were three others—two with successful prostaglandin evacuations. Two patients underwent

§A pair of 850 and 830 gm twins; severe preeclampsia; transverse lie.

hysterotomy because of hemorrhage. Six of the group had had ultrasound examinations, and in two, extensive retromembraneous dissections were clearly visible, whereas in four there was no finding of abruptio placentae. Although there were only two positive scan findings of abruptio placentae, four of the six patients who were scanned did indeed have old adherent clots found at delivery.

All these previable neonates died intrapartum or in the immediate neonatal period as expected. Only two pregnancies were maintained >2 days from admission to delivery, which included one case with a sonographically visible extensive retromembraneous dissection seen at 17 weeks' gestation with eventual hysterotomy at 20 weeks plus 2 days for hemorrhage and another case with spontaneous rupture of membranes at 20 weeks, subsequent chronic spotting, and then hemorrhage at 24 weeks plus 3 days, also requiring hysterotomy. Among these patients only the one with severe preeclampsia had thrombocytopenia (140,000/mm^3), and none had elevated prothrombin time or partial thromboplastin time values. None of these patients were given tocolytics.

Seventy-two patients who were delivered between 25 weeks plus 6 days and 36 weeks plus 6 days made up the preterm group of patients. Demographic data are presented in Table II. In comparison to the term pregnancies, there was no difference in age but a statistically significant increase in the number of known cigarette smokers. A χ^2 analysis of smoking/nonsmoking or unknown and preterm/term abruptio placentae in a two-by-two table yielded a value of 5.162 ($p < 0.025$). There was also a significantly increased proportion of preterm patients reporting a poor obstetric history, that is, 17, or 23.6%, had had only abortions or preterm deliveries without surviving infants ($\chi^2 = 10.279$ at 3 df ($p < 0.025$).

Presenting symptoms are shown in Table III. A review of the composite data in this table underscores the wide range of presenting symptoms in abruptio placentae and the variation of those symptoms according to gestational age groups. Of note is the 10% incidence of back pain, which thus appears to be a quite specific signal for abruptio placentae. The total of the "chronic spotting," "back pain" and the totaled "bleeding" rows equals 85 patients, which implies that the remaining 45 of 130 or about one third of patients presented without symptoms that would ordinarily imply that an abruptio placentae was occurring or about to occur. This proportion was verified by tabulation of the "initial diagnosis" entries derived from the initial history and physical, wherein 48 of the 72 preterm patients (66.7%) were diagnosed to have abruptio placentae or marginal sinus bleeding at admission. Only four patients in this preterm group (and therefore six in the entire series) had blood pressure values ≥130/90 mm Hg. The completed

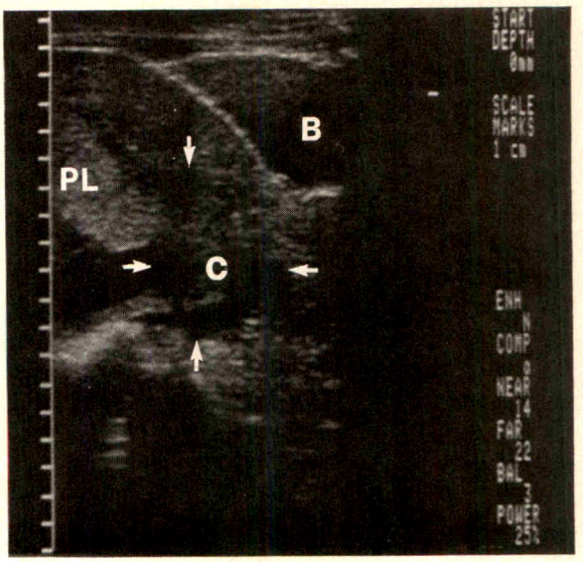

Fig. 2. This longitudinal linear-array ultrasound photograph shows the bladder *(B)*, a low-lying placenta *(PL)*, and the fluid and solid echoes of an abruption clot *(C)*, outlined by *arrows*. The placental edge is elevated by some dissection of the blood underneath.

Table IV also shows the delivery methods for the three gestational age groups. In the preterm group 57% of the gravid women were delivered by cesarean section and, of these, 80.5% on an emergency basis for either hemorrhage or fetal distress. Twenty-three patients received transfusions of 1 to 4 U of blood with a total of 48 U transfused. Seventeen of these patients receiving transfusions were delivered by cesarean section compared to six with vaginal deliveries. Platelet counts were $<150{,}000/mm^3$ in six patients, three of whom were hypertensive. The mean hemoglobin drop (admitting value to nadir value) was 3.78 ± 1.36 gm/100 ml for these six compared with 1.88 ± 1.27 gm/100 ml for 55 others with available data.

A comparison of the immediate neonatal condition of the infants delivered vaginally compared to those by cesarean section in the preterm group is given in Table V.

Appropriately timed ultrasound examinations were performed in 48 of the 72 preterm patients. Of the 24 patients not scanned, 13 were delivered the day of admission and 22 within 5 days of admission. The delivery method for 17 of the 22 was cesarean section with assorted indications—two with active labor (a 1420 gm fetus in transverse lie and 830 and 850 gm twins); eight for hemorrhages; six for fetal distress; one breech with preeclampsia. There were six vaginal deliveries—five with active labor/cervical dilation and one with preeclampsia. The two patients who were delivered without scans and with hospital stays >5 days both had the abruptio placentae occurring as a late event. One patient had had spontaneous rupture of membranes 44 days earlier, with bleeding commencing the day before cesarean delivery for hemorrhage, and the other patient was hospitalized for hypertension and fetal growth retardation when hemorrhage and fetal distress began on the twelfth hospital day.

In the 48 scanned patients, 33 examinations showed no evidence of abruptio placentae. Six retroplacental clots and six retromembranous clots were visualized, confirming the abruptio placentae diagnosis. Examples of the ultrasound findings are shown in Figs. 1 and 2. One rounded placental contour was noted, which is also a diagnostic feature (but not conclusive) of abruptio placentae.[11] At delivery old clots were reported in 11 of the 33 negative examinations while the remaining 22 patients had delivery record reports of "excessive bleeding," "new clots," "marginal (attached) clots," or the nondescriptive statement of "abruption." Old clots were evident in all 12 patients with sonographically visualized retroplacental or retromembranous clot formation. With use on a hypothetical basis, that the presence of old clots at delivery implies that the diagnosis could theoretically have been made by ultrasound, the sensitivity is derived as 12 of 23 (52.2%). Overall, however, ultrasound examination confirmed the diagnosis in only the 12 of these 48 scanned patients (25%). In a comparison of cases with visualized clots to those with negative findings of abruptio placentae, there were no differences in mode of delivery (Yates' corrected $\chi^2 = 1.21$, $p = 0.27$, in a two-by-two table of visible/negative compared to cesarean section or vaginal de-

14	1	7

those with no evidence of abruptio placentae is shown in Table VI.

In the patients with positive findings of abruptio placentae there were two stillbirths (one before admission and the other within 30 minutes of admission) and three neonatal deaths (480 gm on day 0, 1701 gm at 24 days of age, and 1925 gm on day 12 of life). In the group with no finding of abruptio placentae there were five neonatal deaths: twins of 960 and 850 gm both on day 13 of life, a 1050 gm twin on day 23, 1200 gm on day 11, and a 1315 gm infant on day 0. The 1050 gm twin and the 1315 gm infant both had pulmonary hypoplasia from long-standing oligohydramnios.

In an examination of the use and nonuse of tocolysis in the preterm group, the 72 cases were first divided into subsets according to indications for tocolysis and then reviewed as to success, failure, delivery indications, and finally neonatal outcome. This classification of patients by presenting symptoms is shown in Table VII.

With symptoms of uterine activity at admission, 28 of 50 (56%) were delivered within 3 days compared to eight of 22 (36.4%) if these symptoms were not present. The deliveries at 4 to 10 days (22% versus 13.6%), 11 to 21 days (8% versus 31.8%), and >22 days (14% versus 18.2%) demonstrate the trend of earlier delivery with uterine activity present. With symptoms implying uterine activity (cramping, contractions, spontaneous rupture of membranes, or active labor) 30 of the 50 patients received tocolytic therapy. Those not receiving tocolytic therapy from admission date to delivery remained undelivered from 0 to 44 days, but 15 of the 20 were delivered within 2 days for the indications evident in Table VII, namely, advanced cervical dilation or active labor, fetal distress (which might include hemorrhage), hemorrhage (without fetal distress), or preeclampsia. The five delayed deliveries were at 4, 9, 17, 18, and 44 days, respectively, and included one patient with long-term spontaneous rupture of membranes who had abruptio placentae as a late event in the course of her hospitalization and two others with cramping, spotting, or contractions, who were delivered 4 and 18 days later. Two other patients admitted 17 and 44 days before delivery with spotting and cramping were diagnosed as having limited abruptio placentae—one having a "negative" report for findings of abruptio placentae at delivery and the other with old clots evident at delivery. Insofar as the route of delivery in the uterine activity group is concerned, there was no discernible change as a function of delay to delivery, with a comparable number of cesarean versus vaginal deliveries at each delay interval. Worthy of note is the finding that the delivery after prolonged delay, that is, >10 days, often was prompted by evolution to an "acute" abruptio placentae problem with hemorrhage or fetal distress in seven of 11 (63.6%). In this preterm group with uterine activity symptoms, overall there were 26 cesarean deliveries versus 24 vaginal births.

In the 22 patients with bleeding, back pain, or hypertension as presenting symptoms exclusive of spontaneous rupture of membranes, cramps, contractions, or active labor, 13 (59%) did not receive tocolytic therapy. These 13 patients were delivered within 0 to 34 days from initial hospital admission, eight of them being delivered within 2 days. The remaining five include a patient with a large uterine septum spending 9 days in the hospital before cesarean section delivery for hemorrhage; a patient with twins, bleeding, subsequent advanced cervical dilation, and cesarean section delivery on day 12; the patient with abruptio placentae on day 12 of hospitalization with preeclampsia and an intrauterine growth–retarded fetus; a patient admitted for bleeding 15 days before spontaneous delivery with a marginal abruptio placentae evident at the 36-week delivery; and finally one patient admitted with bleeding 34 days before delivery who had "negative" delivery findings after spontaneous delivery at week 36 plus 6 days. Nine patients admitted with bleeding, back pain, or hypertension symptoms subsequently received tocolytic therapy with admittance-to-delivery intervals of 4 to 85 days—4, 6, 12, 15, 18, 21, 22, 29, and 85, respectively.

In contrast to the uterine activity preterm subset, there were twice as many total cesarean section deliveries compared to the vaginal (15 versus seven compared to the 26 versus 24) but in this nonuterine activity subset there also was not a discernible trend over time with delay to delivery and delivery route. The eight patients who were delivered within 3 days account for

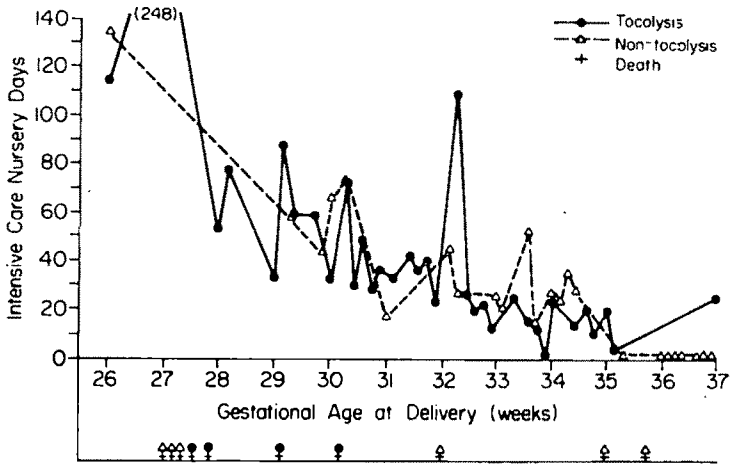

Fig. 3. Length of stay in the intensive care nursery *(ICN)* by days is plotted against gestational age at delivery for infants whose mothers received tocolysis *(solid line)* and those who received no tocolysis *(dashed line)*. The plot show no statistical difference affirming that gestational age is the principal determinant of intensive care unit stay. Fetal or neonatal deaths are shown at the bottom, according to gestational age at birth.

seven of the 14 primary cesarean sections done. Thus once beyond the 3-day delay, there was a rather equal likelihood of vaginal compared to the cesarean delivery at each delay interval and similarly a good chance (six of 14, or 42.9%) that the delayed delivery would be prompted by an emergency situation such as hemorrhage or fetal distress. Four patients in the preterm group presenting without symptoms of uterine activity had admission-to-delivery delay >3 weeks (22, 29, 34, and 85 days). Old clots were evident at delivery in the first three of these patients whereas the delivery examination was "negative" in the patient admitted 85 days before delivery with bleeding diagnosed as a "limited or marginal abruption" not visible on sonogram. In the totaled 72 preterm patients there were 41 cesarean sections (57%) compared to the 31 vaginal (43%) deliveries and 39 (54%) emergency indications of fetal distress and/or hemorrhage.

In Table VIII the 72 preterm patients are segregated according to use or nonuse of tocolysis. Of the 33 patients not receiving tocolysis 10 (30.3%) had delay to delivery of >3 days compared to 26 of 39 (66.7%) patients with use of tocolytics. If the 0- to 3-day delay deliveries (that is, the urgent or emergency cases with advanced preterm labor, significant hemorrhage, or fetal distress) are not considered, the 26 remaining patients receiving tocolysis gained an average of 19.9 ± 18.3 additional days (mean ± 1 SD with SE of the mean = 3.6 days) compared to 17.5 ± 12.3 additional days (mean ± 1 SD with SE of mean = 3.9 days) for the 10 remaining patients not receiving tocolysis. On a statistical basis the gain in days is not significant (Kruskal-Wallis one-way analysis of variance, $p = 0.96$), but there are obvious selection biases in the tocolysis versus nontocolysis divisions—those patients receiving tocolysis were more often those with preterm labor or uterine activity or prodromal symptoms (cramping, spontaneous rupture of membranes, contractions), and those who were delivered within hours or a few days of admission because of hemorrhage were excluded.

When the cases with use of tocolysis are compared to those without its use, there is no discernible change regarding route of delivery (60.6% versus 53.8% by cesarean section). Similarly there is no discernible relationship by tocolysis/no tocolysis divisions nor as a function of delay to delivery, regarding acute indications for delivery, with 17 of 33 (51.5%) and 22 of 39 (56.4%) having fetal distress and/or hemorrhage prompting delivery in the two subsets, respectively. Some bias may be eliminated by considering only those patients delivering after 3 days in the tocolysis/no tocolysis divisions. Again there is no effect on mode of delivery (Fischer's exact test, $p = 1.00$, for two-by-two table of tocolysis/no tocolysis beyond 3 days from admission vs. cesarean section/vaginal delivery) nor on the delivery indications (Fischer's exact test, $p = 0.28$, for two-by-two table of tocolysis/no tocolysis beyond 3 days from admission vs. hemorrhage or fetal distress/other delivery indication). Despite an increased timely use of steroids in the tocolyzed patients, there was no evident reduction in days in the intensive care nursery for the neonates. This is shown in Fig. 3 with an overlay of fetuses with tocolysis compared to the fetuses with no tocolysis and length of intensive care nursery stay in days, as a function of estimated gestational age at delivery.

For the total 72 preterm pregnancies the probability of not being delivered as a function of days from ad-

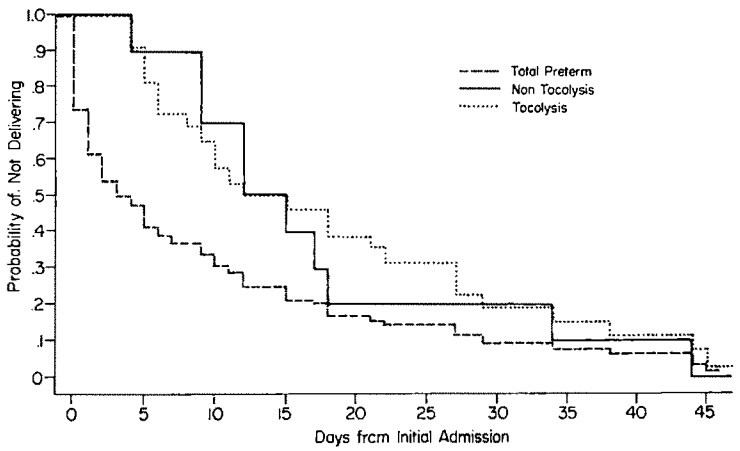

Fig. 4. The plots show the probability curves of not being delivered as a function of days from initial admission for the preterm group. The *dashed line* shows all 72 patients in this group. The *dotted* and *solid* lines show only patients being delivered after 3 days from admission with a comparison of tocolysis (n = 26) and nontocolysis (n = 10) suubsets.

mission is shown in Fig. 4. Twenty-six percent were delivered the day of admission and 50% within 3 days of admission. If those patients who were delivered within 3 days are excluded a more legitimate comparison of the effect of the use of tocolysis compared to the nonuse of tocolysis can be made. Also shown in Fig. 4 is a comparison of the probability of not being delivered as a function of days beyond 3 days for the 10 and 26 patients remaining undelivered at the third day in the nontocolysis and tocolysis divisions respectively. Finally, Fig. 5 shows the probability of delivery by 3, 10, and 21 days as a function of gestational age at presentation for the entire 130 patients in the series.

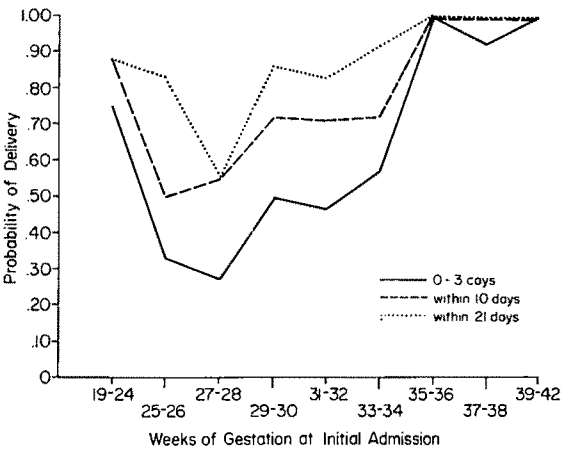

Fig. 5. This plot shows the probability of delivery within 3, 10, and 21 days of admission for the entire study population (n = 130) as a function of gestational age (in 2-week blocks) at initial hospital admission.

Comment

This study examined retrospectively the broad spectrum of bleeding episodes in pregnancy clinically diagnosed as abruptio placentae from 20 to 42 weeks at a level III perinatal center hospital serving principally a middle- to upper-class population. The major emphasis of the report is to contrast the wide individual variations in acuity of abruptio placentae and its course in a day-to-day practice with the more frequent literature and textbook focus on the severe cases of abruptio placentae, which note maternal risk factors, rapid progression to fetal death or distress, and maternal coagulopathy or hypovolemic shock complications. Similarly these sources highlight the urgency mandated to reduce perinatal and maternal morbidity and mortality. In the classic study of Pritchard et al.[7] of severe abruption causing fetal death in utero, 45% of the gravid women were hypertensive. Abdella et al.[9] similarly reported a 26.8% incidence of hypertensive disorders. Within the current study however, only six of the 130 patients (4.5%) presented with hypertension as a notable factor, and hypertension was particularly rare with abruptio placentae occurring at term. Known cigarette smoking was more frequent in preterm versus term abruptio placentae although this finding is somewhat suspect given the large proportion of "unknown" smoking habits. A difference in parity was similarly evident in term versus preterm abruptio placentae, showing that greater parity and particularly only abortions or prior preterm perinatal losses were more frequent in the preterm.

Knab,[5] in reviewing the results of several other authors,[1-5, 11] emphasized that cesarean delivery was without question associated with a decreased perinatal mortality compared to vaginal delivery. In a tabulation of seven reported series, the total perinatal mortality for vaginal delivery was 31.5% compared to 16.7% for ce-

sarean delivery. His recommendation for urgent cesarean delivery was qualified to pertain to moderate and severe cases of abruptio placentae at ≥31 weeks (1500 gm) but included the statement that with mild abruptio placentae also "long delays do not seem to be in the best interest of the fetus." In the present study the overall perinatal mortality was much lower, and logically so, since the broad range of mild to severe abruptio placentae was reviewed. The perinatal losses included the two term infants discussed above, the eight previable infants, and 13 preterm infants for a total of 23 (17%). With corrections (11 infants of <800 gm, a stillborn infant with nonimmune hydrops fetalis and omphalocele, and three infants with pulmonary hypoplasia), the perinatal mortality was eight of 130 (6.2%) with four delivered by cesarean section and three vaginally.

The low perinatal mortality rate in part is derived from inclusion of mild or grade 0 cases of abruptio placentae but also affirms the appropriateness of prompt delivery, especially as was carried out in the patients presenting at term. The results in the term group imply that fetal heart rate monitoring (which at our institution commences immediately on admission and is nearly continuous thereafter) is sufficient to identify those fetuses with fetal distress, so that cesarean sections can be performed in advance of a fetal loss. In the infants delivered at a previable gestational age, the issue of delay compared to the aggressive effort to maintain the pregnancy is moot, since the assignment to this group is self-fulfilling regarding perinatal death. In the preterm delivery group, however, there were 10 patients who were initially admitted in weeks 25 to 26 of pregnancy, who then maintained the chronic abruptio placentae process passing into the preterm group. For the preterm delivery group, clinical managment at admission again included immediate fetal heart rate monitoring with assessment of maternal status. On the basis of clinical course, 36 were delivered within 3 days of admission, but the remaining 36 were maintained with a broad range of days and weeks beyond. A few of this group were discharged after fulfilling the prerequisites of not bleeding for 7 days, not having any fetal heart rate monitoring abnormalities, and not having ongoing uterine cramping or contractions. Under these guidelines, most patients did not qualify for discharge and remained hospitalized under management protocols that included daily heart rate monitoring and liberal use of tocolysis to stop uterine activity. Although, as shown in Table VIII, there was frequent progression to rapid hemorrhage and or fetal distress necessitating delivery (with an overall 56.9.% cesarean section rate), there were no antepartum fetal deaths in this group and only rare low Apgar scores with either vaginal or cesarean delivery (Table V). This further implies that inpatient surveillance for onset of hemorrhage, frequent fetal heart rate monitoring, and immediate access to cesarean delivery, often allowed significant advancement in gestational age without perinatal losses from sudden catastrophic extension of the abruptio placentae. Patience and effort to prolong the pregnancy, combined with this close surveillance, appear to have been very beneficial, albeit on an individual and retrospective assessment—not based on a comparison of immediate delivery to conservative management prospectively.

As a retrospective review in contrast to a prospective randomized treatment protocol, the usefulness of tocolysis with abruptio placentae is not established because the patients receiving tocolysis compared to those not receiving tocolysis differed by presenting symptoms, clinical course, the urgency of delivery indications, and by differences in the various physicians' practice habits. However, if the selection biases regarding use of tocolysis compared to no tocolysis in the preterm group are viewed in some perspective, there appears to be some success in prolonging pregnancy by use of tocolysis. The curves in Fig. 4, showing the probability of not delivering with/without tocolysis if the pregnancy is maintained beyond 3 days from initial admission, at least suggest that the pregnancies with abruptio placentae receiving tocolysis for the usual indications of cramping or contractions can be maintained a number of days commensurate to those of pregnancies in which uterine activity was presumptively not occurring. On the positive side, the results in Table VIII do not support a notion that tocolysis increases the hazard of fetal distress or hemorrhage or that it increases the likelihood of cesarean delivery.

Preferentially, magnesium sulfate was used initially for tocolysis so as not to distort maternal and fetal heart rates as an assay of maternal blood loss or fetal condition. Eventual use of oral ritodrine was a minor goal of treatment, and many patients were maintained chronically on intravenous infusion therapy of either magnesium sulfate or ritodrine, since hospital discharge was infrequent. The study did not encompass a comparison of magnesium sulfate with ritodrine for tocolysis, and when either drug was effective, it was often maintained without changes.

The use of ultrasound to confirm the diagnosis of abruptio placentae shows limited success in the study, and its principal function was to refute the presence of a placenta previa. As would be expected, it played an insignificant, if nonexistent, role in the term group, in which maternal and fetal condition were of principal importance in clinical management. Obviously, in grade 2 abruptio placentae with fetal distress present, ultrasound visualization of the retained clot might be possible and clinically satisfying but is of no consequence in the decision to deliver the patient on an emergency

basis. In the preterm group, visualization of the clot had no impact on the likelihood of cesarean compared to vaginal delivery or on the likelihood of having hemorrhage or fetal distress rather than another indication for cesarean delivery. In any event, even with visualization of a clot, there was a fair chance that the pregnancy could continue for some time, with an absolutely certain diagnosis of abruptio placentae. The ultrasound visualization of abruptio placentae does, however, confound its grading by the Page system (Table I), in that concealed hemorrhage may be present in grades 0 or I.

In summary, this study has shown that there is a wide range of acuity with abruptio placentae, such that in many instances pregnancy can be successfully maintained without evident hazard to mother or fetus. The use of tocolysis with abruptio placentae was found to have no documented deleterious effects and generally was felt to be helpful in prolonging pregnancies with a chronic process of abruptio placentae occurring. Cigarette smoking and previous poor obstetric history were found to be associated with preterm abruptio placentae. Hypertension and thrombocytopenia and clotting dysfunction were rare but seemingly related. Ultrasound visualization of a clot was successful in 25% of cases, with a hypothetical sensitivity of 52%. Finally, inpatient management with frequent fetal heart rate monitoring is credited for allowing advancement in gestational age and reduced perinatal mortality.

Randomized management of the second nonvertex twin: Vaginal delivery or cesarean section

Jaron Rabinovici, M.D., Gad Barkai, M.D., Brian Reichman, M.B., Ch.B., David M. Serr, M.B., Ch.B., and Shlomo Mashiach, M.D.

Tel-Hashomer and Tel Aviv, Israel

Sixty twin deliveries after the thirty-fifth gestational week with vertex-breech and vertex-transverse presentations were managed according to a randomization protocol. Thirty-three parturient women (21 vertex-breech and 12 vertex-transverse presentations) were allocated for vaginal delivery and 27 for cesarean section (18 vertex-breech and nine vertex-transverse). Six pairs of twins in the vaginal delivery group were delivered in a different mode than requested by the protocol (two women underwent cesarean section; in four cases the second twin spontaneously changed to vertex presentation). There were no significant differences between 1- and 5-minute Apgar scores and incidence of neonatal morbidity between the second-born twins in both study groups. Firstborn twins had higher 1-minute Apgar scores than the second-born infants irrespective of route of delivery ($p < 0.05$). No case of birth trauma or neonatal death was recorded. Maternal febrile morbidity was significantly higher in the cesarean section group than in the vaginal delivery group (40.7% versus 11.1%, $p < 0.05$). These results suggest that in twins with vertex-breech or vertex-transverse presentations after the thirty-fifth week of gestational age the neonatal outcome of the second twin was not significantly influenced by the route of delivery. (Am J Obstet Gynecol 1987;156:52-6.)

Key words: Twin gestation, delivery, cesarean section

The optimal route of delivery for a twin pregnancy with vertex-breech or vertex-transverse presentations has remained a subject of controversy. Cesarean section has been advocated by some clinicians as the appropriate mode of intrapartum management, since vaginal delivery of the second nonvertex twin was associated with adverse perinatal outcome.[1-7] During the last years several studies have suggested that the second nonvertex twin weighing >1500 gm can be delivered vaginally with as much safety as by cesarean section.[8-10] These contradictory results have been partly attributed to the retrospective design of all previous studies.[9,11]

This report presents our experience with the randomized intrapartum management of vertex-breech or vertex-transverse twin gestations. The protocol was instituted in order to evaluate the influence of the route of delivery on neonatal and maternal outcome.

Material and methods

Selection and preparation of patients. The study period ranged from March 1, 1983, to September 30, 1985. The staff of the Department of Obstetrics and Gynecology at the Chaim Sheba Medical Center was instructed to consider every patient with a twin pregnancy presenting to the labor ward for participation in this study. Fetal confinements were assessed by a plain abdominal x-ray film and by an ultrasound examination that included estimation of fetal weight, amniotic fluid volume, localization of the placenta and umbilical cord, and exclusion of gross fetal anomalies.

The following inclusion criteria were requested: twin pregnancy with spontaneous or induced labor and with both twins alive, the first fetus in vertex presentation and the second twin in breech presentation or in transverse lie, estimated gestational age between 35 and 42 weeks, presumably normal fetal anatomy, no signs suggestive of acute placental insufficiency or abruptio placentae, normal amniotic fluid volume, normal fetal heart rate testing, no maternal or obstetric indications for a specific route of delivery (such as cephalopelvic disproportion, previous uterine surgery, or uterine anomalies that contraindicated vaginal delivery), and cervix <7 cm dilated. Cervical dilatation was included as a criterion in order to allow sufficient time to prepare for a cesarean section.

The route of delivery was determined after the fulfillment of the above criteria according to a protocol that was changed randomly by a noninvolved person without prior notice on a time basis. If the parturient patient was found suitable to participate, the senior

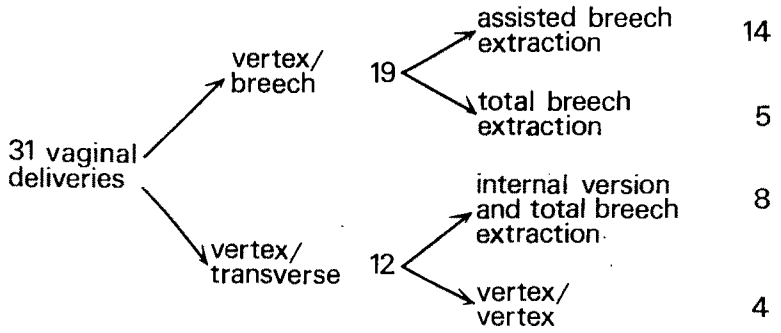

Fig. 1. Presentations and mode of delivery of the 31 pairs of nonvertex twins delivered vaginally according to randomized allocation. (Note that two women allocated to the vaginal group but delivered by cesarean section were not included.)

obstetrician inquired about the proposed mode of delivery and labor was managed accordingly. The protocol of this study was approved by the local ethical comittee of the Chaim Sheba Medical Center.

In order to achieve uniformity in the management of labor the following guidelines were established: In the cesarean section group the delivery was undertaken through a lower-segment transverse uterine incision. The preferred mode of anesthesia was epidural analgesia, but this depended ultimately on the anesthesiologist's decision. In the group delivered vaginally the progress of labor was evaluated by Friedman curve. Fetal monitoring consisted of continuous electronic recording by external ultrasonic monitoring and by internal cardiotocography after rupture of the membranes. The heart rates of both twins were recorded concomitantly. After the delivery of the first twin and before rupture of the second amniotic sac the lie of the second fetus was assessed clinically and confirmed by real-time ultrasonography.

With the fetus in breech presentation an assisted breech delivery was performed. Signs of acute fetal distress at this stage of labor or inadequate progress despite controlled oxytocin drip (5 IU/500 ml of isotonic saline solution, maximal rate of 3 ml/min) prompted the performance of a total breech extraction. Artificial rupture of the second amniotic sac was undertaken as late as possible.

If the second twin was in an oblique or transverse lie after delivery of the first twin, internal version and total breech extraction were performed with the patient under general anesthesia or with epidural analgesia already established. In all cases of vaginal delivery a lateral episiotomy was performed. Vaginal delivery or cesarean section was performed by a resident physician with chief resident and/or senior obstetric staff supervision. Anesthesia and pediatric house staff provided support. Maternal outcome was judged by duration of hospitalization, febrile morbidity, need for blood transfusions, and operative morbidity.

Table I. Presentations of twins at admission

	Allocated route of delivery			
	Vaginal (n = 33)*		*Cesarean section (n = 27)*	
	n	%	*n*	%
Presentation				
Vertex-breech	21	60.6	18	66.7
Vertex-transverse	12	39.4	9	33.3
Indication for admission				
Spontaneous labor or ruptured membranes	29	87.9	22	81.5
Induced labor (postdates)	4	12.1	5	18.5

*Note that six pairs of twins delivered in a mode different from that determined by the study protocol are included in the vaginal delivery group.

The infants were examined immediately by a pediatrician not involved in the study who determined the Apgar scores and fetal weights. Further pediatric management was uninfluenced by the study and was undertaken according to neonatal performance. A cranial ultrasonic examination was performed routinely in infants with birth weights <1500 gm and whenever the test was clinically indicated. Parameters of neonatal outcome included Apgar scores, birth trauma, and neonatal morbidity and mortality.

Statistical analysis. Statistical evaluation of the data was accomplished by the paired and unpaired *t* test, the χ^2 test (with Yates' correction), and the Fisher exact test where applicable. Differences were considered to be statistically significant at $p < 0.05$.

Results

The study population comprised 60 consecutive pairs of twins in the vertex-breech or vertex-transverse presentation before delivery. Twenty-seven women were allocated to the cesarean section group and 33 to the vaginal delivery group. The presentations of the twins

at admission and the indications for admission are shown in Table I. All inductions of labor were performed because of postdatism (after completed 41 weeks of gestation). Two women randomized for vaginal delivery subsequently underwent cesarean section (one because of inadequate progress of labor and another because of heart rate monitoring of the second twin suggesting fetal distress). In four cases in the vaginal delivery group, the second twin changed from transverse to vertex presentation spontaneously after delivery of the first twin (Fig. 1). Five second twins in breech presentation were delivered by total breech extraction because of inadequate descent (one), fetal distress suspected by fetal heart rate monitoring (two), or prolapse of the cord of the second twin after rupture of the membranes (two). In eight parturient women uterine and cervical examinations after internal version and total breech extraction did not reveal any uterine or cervical tears. Delivery of the second twin was performed with the patient under general anesthesia in five of these patients and under epidural analgesia in the remaining three. All women allocated to the abdominal delivery group underwent a transverse lower-segment cesarean section. General anesthesia was used in 12 parturient women and epidural analgesia in 15.

The Apgar scores of the firstborn and second-born twins as well as neonatal data of all deliveries performed according to the allocation protocol are shown in Table II. Birth weights did not differ significantly between the groups and between the firstborn and second-born twins. The 1-minute Apgar scores but not the 5-minute scores of the second-born twins in both groups were significantly lower when compared with those of the firstborn infants. No difference was found between the 1- and 5-minute Apgar scores of the second twins of both groups. The duration of hospitalization was longer in the cesarean section group, but these data were influenced by the prolonged hospitalization of the mothers after abdominal delivery. Mothers and infants are usually discharged 3 to 4 days after vaginal delivery and 6 to 7 days after cesarean section. Thus the incidence of late discharge did not differ significantly between the twins in the different study groups. The incidence of neonatal morbidity was similar in all groups. The data of the six pairs of infants delivered in a mode different from that determined by the study protocol are shown in Table III.

No case of birth trauma to any neonate was recorded. In three infants with birth weights <1500 gm a routine ultrasound examination of the skull did not reveal any abnormal findings. No case of intraventricular hemorrhage was diagnosed and all of the infants were well on discharge.

A significantly higher incidence of maternal febrile

morbidity was observed in the cesarean section group (Table IV). Gestational age at delivery and nulliparity were not significantly different in either study group. Of the eight women who underwent internal version, total breech extraction, and subsequent uterine revision, two had postpartum fever.

Comment

For the last decade obstetricians have performed an increasing number of cesarean sections to deliver second twins in nonvertex presentations.[8, 11] The presented results suggest that in twins with vertex-breech or vertex-transverse presentations after the thirty-fifth week of gestational age the neonatal outcome of the second twin was not significantly influenced by the route of delivery. A low incidence of perinatal morbidity was noted in both groups. This favorable outcome may be related to the antenatal diagnosis of all twins, to the careful intrapartum monitoring of both fetuses, and to the fact that only otherwise uncomplicated pregnancies were included in the study. Antenatal diagnosis of a twin pregnancy is critical for adequate intrapartum cardiotocographic monitoring of both fetuses and the early detection of fetal distress. The poorer outcome for second twins in other studies may have been related to lack of early diagnosis and adequate intrapartum surveillance.[6, 7, 12] Comparable results have been reported in a retrospective study with obstetric management similar to the protocol presented.[13] It is noteworthy that despite the measures taken the 1-minute Apgar scores of the second twins were significantly lower than the scores of the first twin, irrespective of the mode of delivery. We attribute the lack of major birth trauma to the fact that all internal versions were performed with amniotic membranes unruptured and with anesthetic-analgesic medication. The low incidence of induced labor might explain the relatively low incidence of cesarean section for the parturient patients allocated to the vaginal delivery group (two of 33).

Table IV. Maternal data (delivery according to protocol)

	Vaginal delivery (n = 27)	*Cesarean section (n = 27)*

Mean ± SD*	4.9 ± 2.9	8 ± 2
Range	3-13	6-14
Patients discharged on schedule†	18 (66.7%)	13 (48.1%)
Maternal febrile morbidity‡	3 (11.1%)	11 (40.7%)
Maternal anemia (need for blood transfusion)	2	3

*$p < 0.0001$ ($t = 4.49$, degrees of freedom = 52).

†Discharged at 3 or 4 days for vaginal delivery group and at 6 or 7 days for cesarean section group.

‡$p = 0.01$ (Fisher's exact test).

Only parturient women beyond 35 weeks' gestation were considered for the study. The rationale for this criterion was based on the experience of others who failed to demonstrate an increased risk for the second nonvertex twin delivered vaginally with a birth weight of >1500 gm.[9, 14] All of the neonatal deaths and most of the intraventricular hemorrhages reported by others

occurred in infants of lower birth weights.[8, 9] The limit of 35 gestational weeks seems quite reliable as only three infants had a birth weight of <1500 gm. Reliance on prenatal ultrasonic estimation of fetal growth should assist the obstetrician to exclude very low birth weight infants from the potential risks of vaginal delivery.

In this study the incidence of maternal morbidity after cesarean section compared with that after vaginal delivery was high and compares to the incidence in similarly conducted studies.[15] This point is even further stressed if one considers the relatively low incidence of maternal morbidity in women undergoing internal version and uterine revision. Women with abdominal delivery were discharged from the hospital later than patients with vaginal delivery (6 to 7 days as compared to 3 to 4 days), and 48.1% of the parturient women in the cesarean section group compared with 66.7% of the vaginal delivery group, left the hospital at the appropriate time (nonsignificant difference) (Table IV).

In four of 12 pairs of twins with vertex-transverse presentations, the second fetus spontaneously changed to vertex presentation during the course of vaginal delivery. These findings and the good results reported by others undertaking external cephalic version after the birth of the first twin[16] suggest that during vaginal delivery of vertex-nonvertex twins some second-born fetuses may present in vertex position at the time of expulsion. There is general agreement that vaginal delivery is appropriate for vertex-vertex–presenting twins.[3, 13]

The favorable outcomes of the second-born twins delivered vaginally as well as the established maternal risks associated with cesarean section support the contention that in selected twin pregnancies with vertex-breech or vertex-transverse presentations at a gestational age of 35 weeks or more, a vaginal delivery can be performed without increased risk to either mother or infant. We appreciate that because of the rarity of adverse outcome in this study the possibility of a type 2 statistical error that can be attributed to the sizes of the subpopulation should be taken into account. We shall continue this study to expand the groups and to strengthen the data. In recent articles the authors[8, 9, 11, 13] voiced their hope of settling the controversy on the appropriate management of the second nonvertex twin by randomized prospective studies. Our results suggest similar neonatal outcome irrespective of the route of delivery of these infants. It is hoped that the presented data will encourage others to conduct similar prospective studies or multicenter studies in order to substantiate our findings in larger study groups.

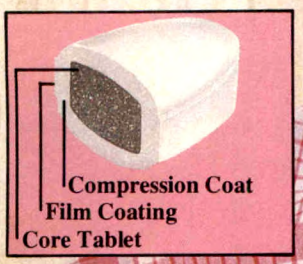
Natalins Rx

Multivitamin and Multimineral Supplement with 1 mg Folic Acid

The Only Prenatal Vitamin with No Artificial Color or Flavor from Synthetic Sources

The Recipe for Prenatal Good Health



Good things are made from the finest ingredients. And the ingredients for maintaining good prenatal health make NATALINS Rx a standout . . . inside and out.

NATALINS Rx is the first and only prescription vitamin and mineral supplement with "natural" color and flavor. It contains all the mandatory and optional vitamins and minerals, plus copper and zinc, both important in the metabolic process.

Unique NATALINS Rx Construction Aids Compliance and Maintenance of Good Health

An elliptical tablet shape and a cellulosic film coating that becomes slippery when wet allows for easier, more comfortable swallowing—aiding patient compliance. Beneath the special coating, a central "core tablet" stores iron for delayed release, reducing the risk of stomach upset.

NATALINS Rx . . . the "Natural" Choice for Prenatal Good Health.

NATALINS® Rx

Ingredients	Natalins Rx

Copper, mg	2	100
Zinc, mg	15	100
Artificial color	none	
Artificial flavor	none	

Natalins Rx is a multivitamin, multimineral supplement for pregnant or lactating women. Daily dose: 1 tablet or as prescribed.
Contraindications: Natalins Rx should not be prescribed in patients with hemochromatosis or patients with Wilson's disease.
Caution: Pernicious anemia should be excluded before using this product. In patients with kidney stones, the calcium content of Natalins Rx tablets should be considered before prescribing.
Supplied: Bottles of 100 and 1,000.

In intra-abdominal infection...

Consider

Fact No. 1

Bacteroides fragilis is the major anaerobic pathogen[1]

"The most common anaerobic organism is B fragilis, isolated in 80 to 95 percent of patients with colorectal perforation."[2]

Fact No. 2

Against *B fragilis*, CEFOTAN has equal in vitro activity to cefoxitin*[3-10]

Gorbach, Quintiliani, Neu, and others have studied a total of more than 900 isolates of *B fragilis* and determined that CEFOTAN and cefoxitin have equal in vitro activity.*[3-10]

Fact No. 3

Intra-abdominal infection is polymicrobial

Tally and Gorbach report that *B fragilis* is the major anaerobic pathogen, while *Escherichia coli* is the primary aerobic isolate.[11]

Fact No. 4

CEFOTAN has superior gram-negative activity compared with cefoxitin[12]

"...spectrum of activity [of CEFOTAN] is distinguished by having the same anti-anaerobe[†] effect as cefoxitin coupled with enhanced activity against Esch. coli and other Enterobacteriaceae."[13]

—C.J.L. Strachan—

*In vitro activity does not necessarily correlate with in vivo effectiveness.

†Most strains of *B distasonis*, *B ovatus*, and *B thetaiotaomicron* are resistant to CEFOTAN.

© 1986 ICI Americas Inc

The Facts

Fact No. 5

CEFOTAN is cost-effective

Twice-daily CEFOTAN can save 45% in treatment costs and single-dose prophylaxis with CEFOTAN saves 63% when compared with a three-dose regimen of cefoxitin.‡

Conclusion

The facts now favor CEFOTAN

CEFOTAN is an ideal agent in the treatment of intra-abdominal infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis*, but not *B distasonis*, *B ovatus*, or *B thetaiotaomicron*.

As active as cefoxitin against *Bacteroides fragilis*—the most common anaerobe in intra-abdominal sepsis—CEFOTAN provides superior gram-negative coverage and is particularly active against *E coli* and other common gram-negative pathogens.

In intra-abdominal infection due to indicated organisms Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

Please see the following page for brief summary of prescribing information.

‡Based on overall costs of antibiotic preparation and delivery[14] for comparable regimens: Treatment—CEFOTAN, 2 g × 2; cefoxitin,[15] 2 g × 4. Prophylaxis—CEFOTAN 2 g × 1; cefoxitin,[15] 2 g × 3.

CEFOTAN IM/IV
(cefotetan disodium)

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

GOOD NEWS ABOUT MALPRACTICE!

Informed Consent™ Systems was developed by doctors and lawyers to help eliminate doctor/patient litigation.

The **Informed Consent™ System** is:

- A *Videotape* designed to inform a patient about surgical procedures in an easy-to-understand format.
- A *Legal Support Service* designed to supply materials which show that the duty to obtain [the patient's] informed consent was discharged.

—SPANISH FORMAT AVAILABLE—

Features:

- Videotapes explain surgery in a clear and uncomplicated manner.
- Videotapes explain risks and complications but are not designed to scare patients.
- Videotapes use diagrams and illustrations instead of actual photographs.
- Legal Support Service stores evidential materials and provides access for later courtroom use.

Informed Consent™ Systems specialty areas:

◆ obstetrics/gynecology ◆ orthopedic ◆
◆ otolaryngology ◆ urology ◆
◆ endarcardiology/vasiculary ◆
◆ general surgery ◆

FOR VULVOVAGINAL CANDIDIASIS

Think 3 Days*

Boston University School of Medicine
Dept. of Obstetrics & Gynecology

presents

A REVIEW COURSE AND UPDATE IN OBSTETRICS AND GYNECOLOGY—1987

Course Director
Leonard J. Cibley, M.D.

A distinguished faculty will emphasize controversial topics and management of patients in broad areas of obstetrical and gynecological practice. This program should prove of interest to the practicing obstetrician-gynecologist, pediatrician, resident-in-training, as well as to the nurse-midwife and nurse practitioner.

March 30 — April 1, 1987

Royal Sonesta Hotel
Cambridge, Massachusetts

OB/GYN
Central New Jersey

BC/BE physician who has recently completed or is completing a university affiliated residency wanted to join a solo practitioner in central New Jersey.

Association leading to partnership, malpractice insurance paid. Competitive salary.

Send C.V. and letter to:

Charles M. Fleisch, D.O., FACOG
415 Avenel Street
Avenel, NJ 07001

or call:
201-636-2122

Join the Group in Minneapolis.

Outstanding career opportunity combining superior care with professional growth. Join progressive department of 20 physicians, 12 nurse-midwives and 6 ob/gyn nurse practitioners delivering 300 babies each month and providing family planning, infertility, high-risk obstetrics, laser surgery, colposcopy, ultrasonography, laparoscopy and maternal/fetal medicine in one of America's leading metropolitan areas.

Comprehensive benefits including professional liability, four weeks vacation, two weeks conference leave, sick leave, medical coverage, dental coverage, life insurance, disability and retirement plans. Opportunities for teaching and university affiliation. Please send c.v. to: **M. Aksoy, M.D., Chairman, Department of Obstetrics and Gynecology; GROUP HEALTH, INC.; 2829 University Ave. S.E., Suite 220; Minneapolis, MN 55414.**

Maternal-Fetal Medicine

Board certified/eligible PERINATOLOGISTS required for large volume obstetric services (3,000-6,000 deliveries per year).

Opportunities exist both to join and create high risk obstetric services at various Kaiser Permanente Medical Care Centers located in Southern California. University affiliations and clinical research is encouraged.

Excellent benefits are offered including liability coverage, medical and dental coverage, vacation and sick leave, continuing education and retirement program. Partnership consideration available after two years full time employment.

Please write, including your curriculum vitae and three professional references to:

The Only 3-Day Cream*

Think

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

Predictors of vaginal delivery in patients with a previous cesarean section, who require oxytocin

Richard K. Silver, M.D., and Ronald S. Gibbs, M.D.
San Antonio, Texas

Prospective analysis of 98 consecutive patients at term pregnancy with one previous cesarean section, who received oxytocin during a trial of labor (34 inductions, 64 augmentations), was undertaken to identify specific factors associated with successful vaginal delivery. The overall vaginal delivery rate was 59.2%. Comparing route of delivery in the induction and augmentation groups separately revealed no significant differences in maternal height, weight, or parity, duration of membrane rupture, length of oxytocin treatment or maximum dose, cervical examination on admission or before oxytocin treatment, or use of conduction anesthesia. A previous vaginal delivery favored repeat vaginal delivery in patients with augmentation while a nonrecurrent indication was significantly associated with vaginal delivery in all patients. After the beginning of oxytocin augmentation, the cervical dilatation rate was 1.82 cm/hr in patients delivered vaginally, compared with 0.18 cm/hr in those requiring cesarean section ($p < 0.001$). Any cervical dilatation during the first 2 hours of augmentation was associated with more frequent vaginal delivery: 24 of 40 vaginal deliveries (60%) versus six of 24 cesarean sections (25%, $p < 0.01$). Discriminant analysis correctly identified route of delivery in 85.3% of those with induction and 87.5% of patients with augmentation. During a trial of labor, oxytocin induction or augmentation is effective in a majority of patients. Furthermore, an early response during augmentation is of predictive value when such patients are being managed. (AM J OBSTET GYNECOL 1987;156:57-60.)

Key words: Oxytocin, trial of labor, cervical dilatation rate

Although the revised recommendations of the American College of Obstetricians and Gynecologists[1] support oxytocin use during a trial of labor, wide application of this practice has not been observed. Many reviews of vaginal delivery after cesarean section include an analysis of oxytocin use.[2-8] In general, patients receiving oxytocin in these series were delivered vaginally as often as women laboring spontaneously. However, less than half of the women in each of these retrospective studies actually received oxytocin (range 2% to 41%). Also the indications for oxytocin and/or the methods of administration were infrequently defined. Finally all of these reports introduce the potential bias of patient self-selection (for trial of labor), which may impact on route of delivery and overall success rate. The present prospective study was undertaken to determine whether oxytocin is effective for induction or augmentation in patients undergoing a trial of labor and to identify those factors predictive of successful vaginal delivery.

Material and methods

One hundred consecutive patients with singleton pregnancies at term and a history of one low-transverse cesarean section, receiving intrapartum oxytocin, were included in this prospective study from March 1983 through February 1985. Thirty-four patients underwent induction of labor and 64 augmentations were performed. Indications for induction included spontaneous premature rupture of the membranes (n = 17), impending postdates (n = 6), pregnancy-induced hypertension (n = 5), diabetes mellitus (n = 5), and intra-amniotic infection (n = 1). All patients were delivered at Medical Center Hospital in San Antonio, Texas. Two patients received oxytocin during the second stage only and were excluded from further analysis. No other patient with a previous cesarean section, who required oxytocin, was excluded during this study interval.

Criteria for induction of labor included an obstetric indication for delivery, the absence of regular contractions, and pretreatment dilatation <3 cm, whereas labor augmentation required dilation ≥4 cm, regular uterine activity, and no cervical change during the preceding 1 hour. For induction, oxytocin was administered by doubling the initial dose of 1 mU/min every 30 minutes to a maximum dose of 64 mU/min; for augmentation, the same initial dose was increased by 1 mU/min every 30 minutes. All patients had intra-

uterine pressure catheters placed before oxytocin administration, and Montevideo Units were calculated to assess response to oxytocin. After vaginal delivery, the integrity of the lower uterine segment was verified by examination in all cases.

Prenatal, intrapartum, and delivery variables were recorded for each patient. Analysis of data was accomplished with the Statistical Package for Social Sciences (X),[9] including χ^2 analysis for discrete variables and Student's *t* test (two-tailed) for continuous data and stepwise discriminant analysis.

Results

The overall vaginal delivery rate was 59.2% (inductions, 52.9%; augmentations, 62.5%). Selected obstetric variables associated with a successful trial of labor are summarized in Tables I and II. There were no significant differences in maternal height (expressed as either mean height or number of women <60 inches tall in each group), weight, or parity, when route of delivery was compared among all patients. In this same comparison, duration of membrane rupture, length of oxytocin treatment or maximum dose, cervical examination on admission or before oxytocin treatment, and use of conduction anesthesia were similar among both the induced and augmented groups. A positive association with previous vaginal delivery was limited to the augmented group (85.7% vaginal delivery rate with this history), while a nonrecurrent indication favored vaginal delivery in all patients. Nonrecurrent indications included malpresentation (n = 15), fetal distress (n = 11), pregnancy-induced hypertension (n = 6), multiple gestation (n = 3), and placenta previa (n = 1). Analysis of women with a lower birth weight at cesarean section than in the present pregnancy demonstrated that a larger infant during the current pregnancy did not preclude vaginal delivery. Overall, of the 62 women with larger infants, 30 were delivered vaginally. However, among patients with augmentation, a lighter infant during the current pregnancy favored a successful trial of labor (84.0% versus 48.7%, $p < 0.01$), and infants born by cesarean section were heavier than the neonates delivered vaginally (3548 versus 3280 gm, $p < 0.05$).

Table III. Cervical dilatation rates among patients with augmentation compared by route of delivery

Labor interval	*Dilatation rate (cm/hr, mean ± SD)*		*p*
	Cesarean (n = 24)	*Vaginal (n = 40)*	
Onset of active labor to oxytocin treatment	0.29 ± 0.24	0.39 ± 0.21	=0.08
Oxytocin treatment to complete dilatation or labor arrest	0.18 ± 0.21	1.82 ± 2.01	<0.001
First 2 hr of oxytocin treatment	0.18 ± 0.28	1.19 ± 1.23	<0.001

Although oxytocin was stopped or reduced more frequently among patients with augmentation requiring cesarean section, all patients demonstrated at least 150 Montevideo Units for two consecutive hours, without cervical change, before abdominal delivery. Reasons for reducing or stopping oxytocin included fetal heart rate abnormalities (n = 13), hypercontractility (n = 6), or both (n = 6).

Significant associations between progressive cervical effacement or descent of the presenting part and route of delivery were not identified. However, rates of cervical dilatation, before and after oxytocin treatment, were significantly different when compared by route of delivery. Three of these interval cervical dilatation rates are shown for the patients with augmentation in Table III. Before oxytocin treatment, the vaginal delivery group had a slightly increased rate of dilatation

($p = 0.08$). After augmentation, this same group had dilatation at 1.82 cm/hr for the remainder of active-phase labor, compared with only 0.18 cm/hr in those patients delivered by cesarean section ($p < 0.001$). Even during the first 2 hours of augmentation (when a maximum oxytocin dose of only 4 mU/min could be administered), patients destined to be delivered vaginally demonstrated significant cervical change. In contrast, dilatation rates during the first 2 hours of induction ($n = 34$) did not discriminate between route of delivery in that group of patients (vaginal, 0.30 cm/hr; cesarean, 0.22 cm/hr).

Table IV details the vaginal delivery rates as a function of cervical change during the first 2 hours of augmentation. Any change in dilatation during this period was associated with vaginal delivery in 75% of cases, while no change was associated with cesarean section in the same percentage of patients. Successively higher rates of dilatation enhanced the predictive value for vaginal delivery. Overall, in 24 of the 40 vaginal deliveries (60%), there was some degree of cervical change during this interval; this is compared with only six of the 24 cesarean sections (25%, $p < 0.01$).

Discriminant analysis was used to identify variables that predicted route of delivery among patients with both induction and augmentation. Initially both prospective (that is, known before oxytocin treatment) and retrospective (that is, known after delivery) variables were allowed to enter the model. Variables selected included cervical dilatation rates before oxytocin and in the first 2 hours after oxytocin, cervical examination (dilation) before oxytocin, active-phase dilatation rate, and maximum oxytocin dose. In this analysis, route of delivery was correctly identified in 29 of the 34 patients with induction (85.3%) and in 57 of the 64 patients with augmentation (89.1%). Next, only dilatation rates before oxytocin and in the first 2 hours after oxytocin were allowed to enter the model for the augmented group. These two prospective variables correctly identified 80% of the cesarean deliveries and 66.7% of those women with successful trials of labor.

Measures of morbidity included the incidence of antepartum and puerperal infection, intraoperative complications including uterine dehiscence, the need for blood transfusion, and any neonatal 5-minute Apgar score <7. Most complications were incurred by the patients with failed trials of labor. The diagnosis of intraamniotic infection was made in five women, three of whom were delivered by cesarean section. Nine of the 11 cases of endometritis were also encountered among cesarean section patients. All infections responded to appropriate antibiotic therapy. Two patients were noted to have uterine "windows" that had been asymptomatic during labor. These were repaired without complication at the time of cesarean section. Two other patients received a blood transfusion in the postoperative period. All neonatal 5-minute Apgar scores were ≥7.

Table IV. Cervical dilatation rate during the first 2 hours of augmentation and associated rates of vaginal delivery

Cervical dilatation rate (cm/hr)	*No. of patients with this rate (n = 64)*	*Patients delivered vaginally (%)*
≥0*	64	62.5
≥0.25	42	78.6
≥0.50	28	85.7
≥0.75	26	88.5
≥1.0	20	100.0

*Sixteen patients demonstrated no cervical dilatation during this period and only 25% of this group were delivered vaginally.

Comment

The practice of vaginal delivery after previous cesarean section has been a standard of care at this institution for the last 16 years.[10] Lavin et al.[11] reviewed the literature on trial of labor from a 30-year period and concluded that oxytocin use might increase the risk of uterine rupture. Other authors[2,4,6,8,12] and the American College of Obstetricians and Gynecologists have suggested that oxytocin can be used safely without increased maternal or fetal risk. Although the present study was not designed to address safety, we observed no excessive morbidity in our patients, even among women with failed induction or augmentation of labor.

Certain relationships between clinical history and route of delivery among patients undergoing a trial of labor have been confirmed in the present investigation. Although patients with previous arrest of labor may be at increased risk for repeat cesarean section, 50% of our patients with augmentation with this history were delivered vaginally. Hypothetically, if oxytocin was not used, as advocated by Jarrell et al.,[13] most or all of the 64 patients with augmentation would have required abdominal delivery secondary to hypocontractile labor dysfunction. Alternatively, oxytocin use limited to women with nonrecurrent indications, as proposed by Benedetti et al.,[4] would have resulted in 19 more cesarean sections in this series. In reviewing the effect of previous indications on route of delivery, Clark et al.[14] also concluded that exclusion of patients with recurrent conditions was unjustified.

A history of at least one previous vaginal delivery favors a successful trial of labor. Because of standard selection criteria (one previous cesarean section only) and the parity of our patients (median = 1), 72.5% had not experienced a vaginal delivery. Therefore, the recognized advantage of a previous vaginal delivery is lim-

ited to a minority of women and should not be used as a selection criterion for trial of labor or oxytocin use.

Seitchik and Rao[15] analyzed 58 patients with "presumed" recurrent indications (failed progress in labor or cephalopelvic disproportion) who presented for a trial of labor in a subsequent pregnancy at this institution. It was apparent that the original diagnosis was not predictive of repeat abdominal delivery, even in those patients carrying larger infants during the current pregnancy. In our patients with augmentation, although absolute birth weight was significantly different when route of delivery was compared, half of our patients with larger infants in the current pregnancy also were delivered vaginally. It appears that birth weight estimates in excess of birth weight with previous cesarean section should not exclude patients from a trial of labor or use of oxytocin.

Our analysis of cervical dilatation rates before and after oxytocin administration was performed to identify prospectively those patients likely to be delivered vaginally. For patients with augmentation, we selected the first 2 hours of oxytocin treatment for two reasons. Previous work by Seitchik and Castillo[16] noted that most patients with augmentation required less than 4 mU/min to achieve adequate contractility. With this expectation, those patients requiring dose increments each 30 minutes would reach 4 mU by 90 minutes. An additional 30 minutes would then be available to observe the pharmacologic effect of that dosage. Second, the predictive value of this posttreatment observation is limited by how quickly a trend can be detected. For patients with augmentation, any cervical change in the first 2 hours predicted route of delivery in a majority of patients. However, 16 patients without cervical change during this interval still were delivered vaginally. It is apparent that some patients need a period of observation >2 hours before augmentation is considered ineffective. In contrast, patients achieving a minimum of 0.5 cm/hr during these first 2 hours are very likely to be delivered vaginally. This information may be helpful to the clinician attending a trial of labor, during which active-phase arrest occurs and oxytocin is considered.

In summary, oxytocin induction or augmentation during a trial of labor is effective in a majority of patients and is recommended in response to standard obstetric indications. Furthermore, early cervical dilatation during augmented labor has predictive value regarding route of delivery.

The effect of percutaneous estradiol and natural progesterone on postmenopausal bone loss

Bente J. Riis, M.D., Karsten Thomsen, M.D., Verner Strøm, M.D., and Claus Christiansen, M.D.

Glostrup, Denmark

The effect of percutaneous estradiol alone and combined with natural progesterone on postmenopausal bone loss was studied. A total of 57 women who had experienced a natural menopause 6 months to 3 years previously entered the study. After an initial examination the women were allocated in a blinded pattern to treatment with 3 mg of percutaneous estradiol or placebo. The code was broken after 1 year of treatment, and the women receiving estradiol continued with a cyclic addition of progesterone, whereas those receiving placebo continued with placebo. The women were examined every 3 months during the 2 years of treatment. Measurement of the bone mineral content in the forearms (single photon absorptiometry) and the spine and total skeleton (dual photon absorptiometry) showed a significant decrease of 5% to 7% in the placebo group during the 2 years of treatment, whereas it remained constant in all bone compartments in the estradiol group. Addition of progesterone did not influence the results. Biochemical estimates of calcium metabolism changed toward a premenopausal level in the estradiol group but remained unchanged in the placebo group. We conclude that percutaneous estradiol is effective as preventive therapy of postmenopausal bone loss and that addition of progesterone does not influence bone or calcium metabolism. (Am J Obstet Gynecol 1987;156:61-5.)

Key words: Percutaneous estradiol, progesterone, postmenopausal bone loss

After the menopause, women lose bone mineral content at an average rate of 15% to 20% in a 10-year period,[1] which raises the risk that some subjects will manifest osteoporosis later in life. Estrogen replacement therapy has been shown to be the most effective, single modality for the prevention of osteoporosis in women,[2] but it may have some physiologic adverse effects. The metabolic effects of estrogen therapy are influenced by the route of administration. Oral administration is characterized by rapid absorption, a considerable conversion of estradiol to estrone, and a first-pass liver effect, with induction of hepatic protein synthesis. This interaction with liver metabolism may have importance for some of the side effects of estrogen therapy.[3] Percutaneous administration has some advantages because the first-pass liver effect is avoided. Moreover, it has been demonstrated that percutaneous administration of estradiol is effective in ameliorating subjective postmenopausal symptoms.[4] Its effect on bone is, however, unknown.

Combined estrogen-gestagen therapy is an essential feature of postmenopausal hormone replacement therapy.[5] Certain gestagens have, however, been shown to exert adverse effects on lipid metabolism[6] and to influence bone metabolism.[7] Oral administration of micronized progesterone does not adversely affect lipid metabolism.[6] The aim of the present study was to examine the effect of percutaneous estradiol, both alone and in cyclic combination with progesterone, on bone metabolism in early postmenopausal women.

Patients

This study was part of a large double-blind clinical controlled trial carried out at Glostrup Hospital from June 1983 to December 1985. The participants were selected as follows: 9836 questionnaires were sent to women aged 45 to 54 years and 7484 were returned. From information about the last vaginal bleeding, earlier gynecologic operations, and drug intake 558 women fulfilled the following criteria: (1) spontaneous cessation of menstrual bleeding within the preceding 0.5 to 3 years; (2) no treatment with sex hormones or other drugs known to influence calcium metabolism after the menopause. The 558 women were invited to attend a meeting and 397 did attend. After receiving thorough information about the trial 293 gave their written consent to participate (Helsinki Declaration II). The clinical histories were taken and they were given a medical examination including a gynecologic examination with cytologic test, breast palpation, and measurement of resting and supine blood pressures, and blood was sampled. Two hundred seventy women en-

Table I. Clinical data and initial values of bone mass measurements in the two treatment groups (mean ± 1 SEM)

	Hormone group	*Placebo group*
Age (yr)	50.3 ± 0.6	50.5 ± 0.4
Menopausal duration (mo)	15.0 ± 2.2	19.3 ± 1.9
Weight (kg)	61.1 ± 1.8	60.4 ± 1.5
Proximal bone mineral content (U)	38.4 ± 1.1	36.4 ± 1.0
Total body bone mineral content (gm)	3151 ± 126	3011 ± 70
Distal bone mineral content (U)	37.9 ± 1.3	35.7 ± 1.1
Bone mineral density of spine (gm/cm^2)	0.87 ± 0.03	0.87 ± 0.02

tered the trial. All were free of past or present diseases known to influence calcium metabolism or to contraindicate the medications used in the trial. Out of this population 57 women were randomly selected for the present study. After an initial examination the women were allocated to two treatment groups, receiving in a blinded pattern either percutaneous estradiol* (n = 29) or placebo (n = 28) for 1 year. After the first year of treatment, the code was broken; all women receiving 17β-estradiol continued with a supplement of 200 mg of micronized progesterone† from days 13 to 24, and the placebo group continued the placebo cream. The study was thus double blind the first year and single blind the second year.

Trial compliance. Of the 57 women who entered the study 45 women completed all nine examinations (79%). All dropouts took place within the first year of treatment. In the estradiol group nine women left the study: four women because of persistent irregular uterine bleeding; three because of lack of time; one because of aggravation of migraine, and one because of skin irritation at the estradiol application site. In the placebo group two women dropped out because of lack of time and one because of development of hyperthyroidosis. This left 20 patients in the estradiol group and 25 women in the placebo group.

Methods

Bone mineral content of the forearms was measured by single photon absorptiometry, with the use of a Bone Mineral Analyzer 1100 from Mølsgaard Medical (Nuclear Data Corporation). The method estimates bone mineral content in a proximal and a distal region of the forearm with a trabecular bone content of 10% and 45%, respectively (Nilas L, personal communication). The long-term in vivo precision of proximal and distal bone mineral content is 1% and 1.5%.[8] Bone mineral density of the lumbar spine was measured by dual photon absorptiometry on a Lunar Radiation Corporation DP3 scanner. The bone mineral density of the spine was calculated as the bone mineral density values obtained in vertebrae L-2, L-3, and L-4. The precision is 4%.[8] Bone mineral content of the total skeleton was likewise measured by dual photon absorptiometry on a whole-body scanner developed in our laboratory. The precision of the bone mineral content of the total skeleton is 2%.[9]

Intestinal radiolabeled calcium absorption was measured by a modification of the single-isotope technique first described by Marshall and Nordin.[9a] After an overnight fast 10 μCi of calcium chloride Ca 47 was given orally with a carrier dose of 40 mg of calcium ion as calcium chloride and 250 ml of water. Blood samples were taken at 60 and 90 minutes, and the absorbed fraction (the mean values of the results at 60 and 90 minutes) was corrected for lean body mass calculated by the formula of Boddy et al.[9b]

Blood samples were taken and urine was collected in the morning after an overnight fast and tobacco abstinence. Serum estrone and estradiol were measured by radioimmunoassays described elsewhere.[10] Serum alkaline phosphatase was measured enzymatically. Serum calcium was measured by atomic absorptiometry and the serum concentrations were corrected to a serum protein level of 70 gm/L. Fasting urinary hydroxyproline was measured by a spectrophotometric method and corrected for creatinine excretion.

Statistical analysis. For statistical analysis of difference between initial values Student's *t* test for unpaired data was used. To evaluate longitudinal changes in bone mass measurements the initial value was set at 100% and values obtained after institution of treatment were expressed as a percentage of this value. The mean percent change was then used in Student's *t* test for unpaired data.

Results

Table I shows the clinical data and the initial values of bone mass measurements; Table II shows the initial

*Oestrogel cream, 0.6 mg of 17β-estradiol per gram; 28-day cycle: days 1 to 24, 5 gm daily; days 25 to 28, no medication. (Cream applied to the abdominal skin or on the inner side of the thighs or the arm.)

†Utrogestan capsules, 100 mg.

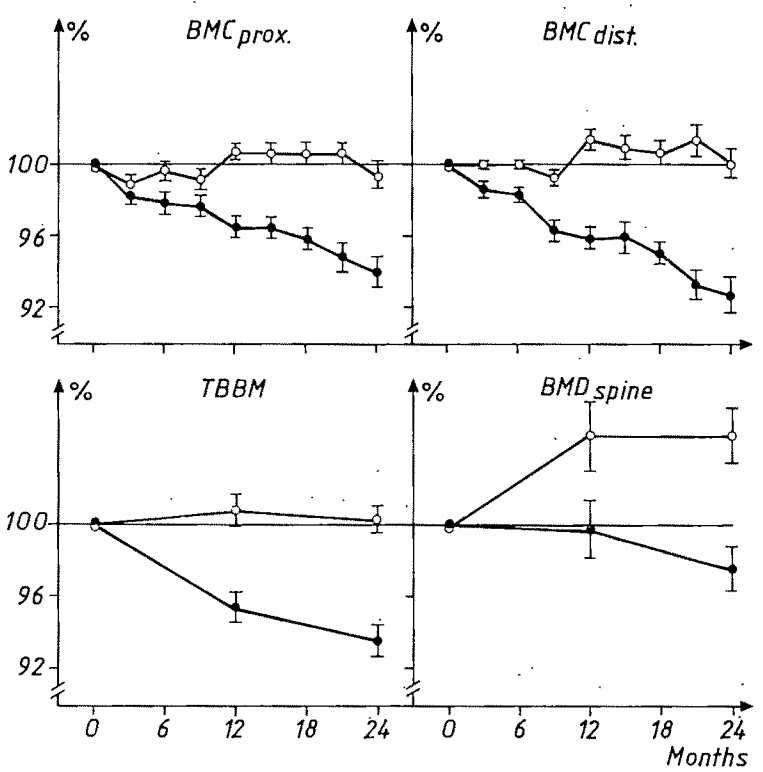

Fig. 1. Mean (± 1 SEM) values of bone mass measurements during the 2 years of treatment. ○ = Hormone group; ● = placebo group. $BMC_{prox.}$ = Proximal bone mineral content; $BMC_{dist.}$ = distal bone mineral content; *TBBM* = total body bone mineral content; BMD_{spine} = bone mineral density of the spine.

values of serum estrogens and biochemical estimates of calcium metabolism. The two treatment groups were comparable.

Fig. 1 gives the mean values of the bone mineral determinations in the four bone compartments. In the placebo group the mean values of all bone mass measurements fell significantly when compared with those in the hormone group, reaching a difference in bone mass of 5% to 7% during 2 years. The addition of progesterone after 1 year of treatment did not influence the results.

Table II shows the changes of serum estrogens, the biochemical estimates of calcium metabolism, and the intestinal radiolabeled calcium absorption. In the hormone group there was a highly significant increase ($p < 0.001$) in serum estrone and estradiol after 3 months of treatment. Thereafter the serum hormone concentrations were virtually unchanged. There was no significant change in serum calcium in either group, whereas both serum alkaline phosphatase and fasting urinary hydroxyproline were decreased in the hormone group compared with the placebo group, reaching significance after 12 months' treatment ($p < 0.01$ to 0.001). Intestinal radiolabeled calcium absorption was unchanged in both groups. None of the variables appeared to be influenced by the addition of progesterone.

Comment

Postmenopausal hormone substitution therapy is widely used, partly to relive climacteric subjective symptoms and partly to prevent postmenopausal bone loss. Percutaneous administration of 17β-estradiol has previously been demonstrated to possess certain advantages over oral estrogen treatment with regard to liver metabolism,[11] and progesterone may have advantages over other gestagens with regard to lipid metabolism.[6]

The present study comprised a representative sample of the Danish population of women who had recently experienced a natural menopause, and the two treatment groups were well matched. We chose a dose of 3 mg of estradiol daily because of its approximate bioequivalence with 2 mg of oral estradiol,[12] which seems to be optimal in terms of preventing bone loss.[13] Studies have shown, furthermore, that a single daily dose of 2 or 4 mg of percutaneous estradiol results in serum estradiol levels that are maintained for 48 hours and that are comparable to serum levels after oral administra-

tion.[14] The dispensing form involves only minor problems: At the beginning of the study most of the women felt it "strange" but thereafter it was well accepted; one woman experienced itching at the application site, without any visible cutaneous sign.

The biochemical calcium metabolic variables changed during treatment in the same way as with oral estrogen treatment,[2] that is, a decrease to the premenopausal level of bone turnover rate.

The methods used for measuring bone mass have a precision that makes them suitable for longitudinal studies. Percutaneous estrogen treatment kept bone mass constant, whereas placebo treatment resulted in a significant loss of bone mineral content in all bone compartments. The mean differences between changes in the two groups, measured either in the total skeleton or locally, were virtually the same after 2 years of treatment. Which bone site (or type of measurement) is the most optimal for studies in osteoporosis has been the subject of heated discussion,[15, 16] but the present study clearly demonstrates that all four measurement systems were able to show the difference between the two groups. It should be noted, however, that the standard error of the mean was lowest for the proximal bone mineral content (0.7% to 0.8% at 24 months) and highest for the bone mineral density of the spine (1.5% to 1.7% at 24 months). This indicates that study of more patients is required to demonstrate the reponse to estrogen treatment if the spine scanner is used than if the forearm scanner is used.

Unopposed oral or percutaneous estrogen treatment for longer periods increases the risk of endometrial cancer, whereas this risk is abolished when a cyclic gestagen component is added.[5] Gestagen also prevents irregular bleeding. In the present study irregular uterine bleeding was observed in the hormone group when treated with estrogen alone, but they had regular bleeding in the second year of treatment. It is also very important that the chosen gestagen exert little or no adverse effects on lipid metabolism; progesterone seems to be such an agent.[6] We conclude that treatment with percutaneous estradiol is a possible alternative to oral administration in terms of preventing postmenopausal bone loss and that addition of progesterone does not influence bone or calcium metabolism.

We thank Laboratoires Besins Iscovesco for supplying Oestrogel cream, Utrogestan capsules, and placebo.

Long-term effects of percutaneous estrogens and oral progesterone on serum lipoproteins in postmenopausal women

Jytte Jensen, M.D., Bente J. Riis, M.D., Verner Strøm, M.D., Lisbeth Nilas, M.D., and Claus Christiansen, M.D.

Glostrup, Denmark

Serum lipids and lipoproteins were examined in a group of 45 healthy postmenopausal women who were treated for 2 years with either 3 mg of percutaneous estradiol (n = 20) or placebo (n = 25). Percutaneous estradiol was given alone during the first year of treatment and in combination with oral micronized progesterone (200 mg) for 12 days of each cycle during the second year. The women were examined every 3 months throughout the 2 years. Percutaneous estrogen therapy significantly reduced total serum cholesterol and low-density lipoprotein cholesterol, whereas no significant differences were observed in serum triglycerides and high-density lipoprotein cholesterol. Addition of oral progesterone during the second year of treatment did not produce any significant alterations in serum total cholesterol or low-density lipoprotein cholesterol, both of which remained significantly reduced. Serum triglycerices remained virtually unchanged, whereas a slight but significant increase ($p < 0.05$) was observed in high-density lipoprotein cholesterol levels at the end of the study period. We conclude that percutaneous estrogen administration produces changes in total serum cholesterol and low-density lipoprotein cholesterol levels similar to those observed after oral estrogen administration. However, the magnitude and time course of the response seem to be modulated by the route of administration. Addition of ora micronized progesterone does not influence the beneficial estrogenic actions on serum lipids and lipoproteins and seems to be a proper "progestogen" in percutaneous estrogen therapy. (Am J Obstet Gynecol 1987;156:66-71.)

Key words: Percutaneous estrogens, serum lipoproteins, postmenopause, oral progesterone

Postmenopausal estrogen therapy is widely used for the treatment of climacteric complaints, and the recognized efficacy of estrogens in preventing postmenopausal bone loss might result in a future rise in the number of women receiving such therapy.

Some metabolic side effects of estrogen therapy seem to be caused by alteration of hepatic functions. Thus changes in lipid and protein metabolism following administration of natural estrogens are believed to be more a consequence of the oral route of administration than of the estrogen treatment per se. Percutaneous administration has the initial advantage of bypassing the portal circulation, and this route of administration has been shown to induce less alteration in the hepatic synthesis of certain lipids[1] and proteins[2] than oral administration. Moreover, physiologic levels of serum estradiol and estrone comparable to the premenopausal range can be attained with percutaneous estrogen administration,[1-3] presumably because percutaneous absorption is slow[3] and the gastrointestinal interconversion of estrogen metabolites is avoided. The effect of orally administered estrogens on serum lipoproteins might be considered advantageous from a cardiovascular point of view, since the therapy increases the levels of high-density lipoprotein (HDL) cholesterol and decreases the levels of low-density lipoprotein (LDL) cholesterol.[4] However, cyclic estrogen/progestogen treatment is recommended, because the addition of progestogen reduces the risk of endometrial hyperplasia[5] and cancer.[6] Unfortunately, some progestogens have been found to reduce[7] or even reverse[8] the beneficial actions of estrogen on serum lipoproteins, although this depends on the type and dose of the implicated progestogen. Recently, "natural" micronized progesterone has been reported to have no adverse effects on lipoprotein metabolism.[8]

Percutaneous estrogen administration has proved to be effective in alleviating climacteric complaints,[2] but the long-term effects on serum lipids and lipoproteins have not been examined in controlled trials, nor has the long-term effect of percutaneous estrogen opposed by oral progesterone on lipoproteins been studied.

In the present placebo controlled study of 45 postmenopausal women, we report on the changes in lipoprotein profiles during 2 years of percutaneous

estrogen therapy opposed for 1 year by oral progesterone.

Material and methods

Participants. This study was part of a large double-blind controlled trial. The participants were selected as follows: of 9836 questionnaires sent to all women aged 45 to 54 years in Copenhagen County, 7484 (76%) were returned. From information about the date of the last vaginal bleeding, earlier gynecologic operations, and drug intake, 558 women fulfilled the following criteria: (1) spontaneous cessation of menstrual bleeding within the preceding 6 months to 3 years; (2) no treatment with sex hormones or drugs known to influence calcium metabolism after the menopause. The 558 women were invited to an information meeting, which 397 attended. After receiving thorough information about the trial, 293 gave their written consent to participate (Helsinki Declaration II). A medical examination was performed, which included a clinical history, gynecologic examination with a cytologic test, breast palpation, and blood sampling. Of the 270 women who entered the trial, all were free of past or present diseases known to influence calcium metabolism or to contraindicate the medications of the trial. Of this population 57 women were randomly selected for the present 2-year study. After three initial examinations the women were allocated to two treatment groups, receiving either cyclic percutaneous estradiol* (n = 29) or placebo (n = 28) in a 28-day cycle. After 1 year of treatment the code was broken and the participants in the estradiol group received oral micronized progesterone† (200 mg) for 12 days (days 13 to 24) of the treatment cycle in addition to the percutaneous estradiol, whereas the placebo group continued to receive the same medication. Hence the study was double-blind throughout the first year and single-blind the second year. No dietary instructions were given. During both treatment years all participants were examined every three months (nine examinations in all). The trial was approved by the Ethical Committee of Copenhagen County.

Trial compliance. Fifty-seven women entered the study, and 45 women completed all examinations (79%). In the estradiol group 9 women left the study, all within the first year. Four women dropped out because of persistent irregular bleedings, three women because of lack of time, one because of aggravation of migraine, and one because of skin irritation at the application site of the estradiol gel (without any visible reaction). Three women in the placebo group dropped out, two because of lack of time and one because thyrotoxicosis developed. The estradiol group finally consisted of 20 women and the placebo group 25 women.

Table I gives the clinical data and initial values of serum lipids and lipoproteins in the two groups of women who completed the study. The groups were comparable.

Methods. Blood samples were drawn in the morning after an overnight fast and tobacco abstinence between days 21 and 24 of the tablet cycle.

Serum lipids and lipoproteins. The HDL lipoprotein fraction was separated from chylomicrons, LDL, and very low-density lipoprotein (VLDL) by the Mg^{2+}/dextran sulphate precipitation technique. Total serum cholesterol and HDL cholesterol were determined by an enzymatic technique with use of an LKB Ultrolab system. The intra-assay and interassay variations were 1% and 2% (total cholesterol) and 2% and 5% (HDL cholesterol), respectively. Serum triglycerides were determined by an enzymatic technique with use of an LKB 8600 reaction rate analyzer. The intra-assay and interassay variations of this method are 5% and 8%.

LDL cholesterol was then estimated according to the procedure of Friedewald et al.[9] The intra-assay and interassay variations of this estimation were 5% and 10%.

Serum estradiol was measured with use of antiserum supplied by Milab, and standards were prepared with use of 17β-estradiol supplied by Merck. The intra-assay and interassay variations were 6% and 15%, and the sensitivity 15 pmol/L.

Serum estrone was measured with use of antiserum supplied by Statens Seruminstitut, and standards were

*Oestrogel: cream, 60 mg of estradiol/100 gm. Days 1 to 24: 5 gm daily, applied to the skin of the abdomen or on the inside of the arms or the thighs.

†Utrogestan: capsules, 100 mg.

Table II. Bleeding pattern during treatment with percutaneous estrogen before and after addition of oral progesterone

Percutaneous estradiol (first year)				*Percutanaeous estradiol plus oral progesterone (second year)*

				Irregular	1	1	Estrogenic

prepared with use of estrone supplied by Sigma. The intra-assay and interassay variations were 11% and 11%, and the sensitivity 100 pmol/L.

Statistical analysis. For each participant the pretreatment value was assessed 100%, and the subsequent measurements were expressed as a percentage of this value. The cumulated therapeutic response was calculated in each participant as the mean of the four measurements during the first and second year of treatment, respectively.

Student's *t* test for paired data was used to test the significance of difference *within* the groups, and Student's *t* test for unpaired data was used *between* the groups.

Results

Uterine bleeding. Table II shows the bleeding pattern in the group receiving percutaneous estradiol before and after addition of oral progesterone. During the year of estradiol monotherapy, eight women (40%) experienced withdrawal bleeding which, however, only occurred regularly in two women (10%). After addition of progesterone, 14 women (70%) experienced regular withdrawal bleeding, whereas only one woman had irregular bleeding.

Three women with irregular bleeding underwent curettage and the endometrial histologic finding was estrogenic in all (Table II). None of the women in the placebo group experienced uterine bleeding.

Body weight. Body weight remained virtually unchanged in the hormone group throughout the 2 years of the study (61.1 ± 8.0 kg initially versus 61.5 ± 8.8 kg in first year versus 61.8 ± 9.3 kg in second year; NS), whereas a significant increase was observed in the placebo group after 1 and 2 years, respectively (60.4 ± 7.5 kg versus 61.1 ± 7.6 kg in first year, $p < 0.005$, and 61.6 ± 8.4 kg in second year, $p < 0.01$).

Serum estradiol and estrone. Fig. 1 shows the changes in serum estradiol and estrone in the two treatment groups at 3, 6, 12, and 24 months of treatment.

Both estrogens were significantly increased in the hormone group at 3 months of treatment ($p < 0.001$). The serum concentrations of both estrogens, however, continued to increase, reaching maximum levels only after 6 months of therapy. This pattern was most pronounced for serum estrone. After 6 months of treatment the serum levels of both estrogens remained virtually constant throughout the rest of the study. The initial estrone/estradiol ratio was >2, but after 6 months of percutaneous estrogen treatment, the ratio was reduced to 1 and this ratio was maintained for the rest of the study.

In the placebo group both estrogens remained within the postmenopausal range throughout the study period.

Serum lipids and lipoproteins. Fig. 2 compares the effect of treatment with cutaneous estradiol, before and after addition of oral progesterone, on serum lipids and lipoproteins with that of placebo. During the first year of cutaneous estradiol therapy the total serum levels of cholesterol and LDL cholesterol were significantly reduced compared to placebo, whereas no significant differences were observed in the serum levels of triglycerides and HDL cholesterol.

Addition of oral progesterone during the second year of treatment did not produce significant alterations in serum total cholesterol and LDL cholesterol, both of which remained significantly reduced in the hormone group. Serum triglycerides remained virtually unchanged during the second year, and no significant differences were observed between the two groups. Throughout the first 6 months after addition of progesterone, HDL cholesterol levels were similar in the two groups, whereas the HDL levels tended to increase during the last 6 months of combined hormone therapy. This increase was significant ($p < 0.05$) at the end of the study period.

Fig. 3 compares the cumulated treatment responses on serum lipids and lipoproteins (that is, mean of four examinations during the first and second year, respectively) in the two groups. The first year of cutaneous estradiol therapy resulted in significantly reduced levels of total cholesterol and LDL cholesterol, both compared to the corresponding initial values ($p < 0.05$, re-

spectively) and compared to placebo ($p < 0.001$, respectively). Serum concentration of triglycerides and HDL cholesterol were significantly increased in the hormone group compared to the placebo group ($p < 0.001$, respectively); however, the changes were not significantly different from initial values. During the second year of treatment, when oral progesterone was added to the percutaneous estradiol, the cumulated response resulted in significant and slightly greater reductions in total cholesterol ($p < 0.01$) and LDL cholesterol ($p < 0.001$) compared to those after percutaneous estradiol alone. However, the differences between the cumulated responses after the first and the second year were not significant. In contrast, no significant changes were observed in serum triglycerides and HDL cholesterol during the second year, although HDL cholesterol levels remained higher in the hormone group. The difference between the cumulated response in HDL after the first and the second year was not significant.

Correlations between the cumulated response of estradiol (that is, mean of four examinations during treatment) and the cumulated change in LDL and total cholesterol (mean of eight examinations), respectively, were significant: estradiol versus LDL, $r = -0.69$, $p < 0.001$, estradiol versus total cholesterol, $r = -0.63$, $p < 0.01$.

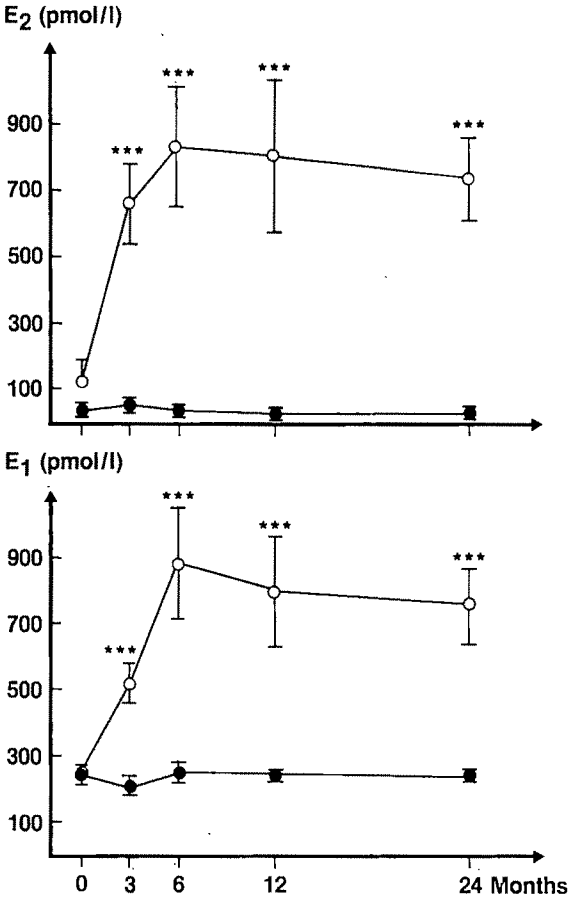

Fig. 1. Serum estradiol *(E_2)* and estrone *(E_1)* during 2 years of treatment with percutaneous estradiol (○) and placebo (●). Values are given as mean ± 1 SEM. Significance of difference: *** $p < 0.001$.

Comment

Both natural and surgical menopause are accompanied by adverse changes in serum lipids and lipoproteins, which are associated with an increased risk of developing cardiovascular diseases.[10] These adverse changes are generally considered a consequence of the ceased ovarian estrogen production, since treatment with oral estrogens reverses the negative trends in lipoprotein profiles by lowering LDL cholesterol and increasing HDL cholesterol.[4] Hence postmenopausal estrogen therapy might be considered advantageous from a cardiovascular point of view, and epidemiologic studies have suggested that postmenopausal estrogen replacement therapy has an overall protective effect against death from ischemic heart disease.[11] In the present study percutaneous estrogen therapy significantly reduced the serum levels of total cholesterol and LDL cholesterol. HDL cholesterol levels tended to be higher after percutaneous estrogens than after placebo, and the cumulated treatment response resulted in a small but significant rise in HDL cholesterol levels. Previous studies of percutaneous estrogen therapy have reported only minor and insignificant changes in serum lipoproteins,[1, 12] despite significant increases in serum estradiol and estrone. These were short-term studies, however, and did not exceed 6 months of therapy. The short duration of treatment probably explains the different findings, since in the present study significant changes in lipids and lipoproteins were only observed after 6 months of treatment. Moreover, the serum levels of both estrogens continued to increase during the first 6 months of percutaneous treatment and only reached the maximum and plateau levels after this period. Furthermore, significant correlations were demonstrated between the cumulated response of estradiol and the cumulated change in LDL and total cholesterol, respectively. Changes in lipoprotein profiles after oral estrogen use have previously been reported to be dose related,[7] and the present response after use of 3 mg of percutaneous estradiol corresponds to the results obtained with 1 mg of oral 17β-estradiol. However, unlike the present study the changes in lipoprotein profiles during oral therapy occurred almost immediately.[7] A possible explanation for the different time/effect course of oral and percutaneous administration of estrogen on lipoproteins might be the route of administration. By the oral route, estrogens are rapidly absorbed with peak plasma concentrations within the first

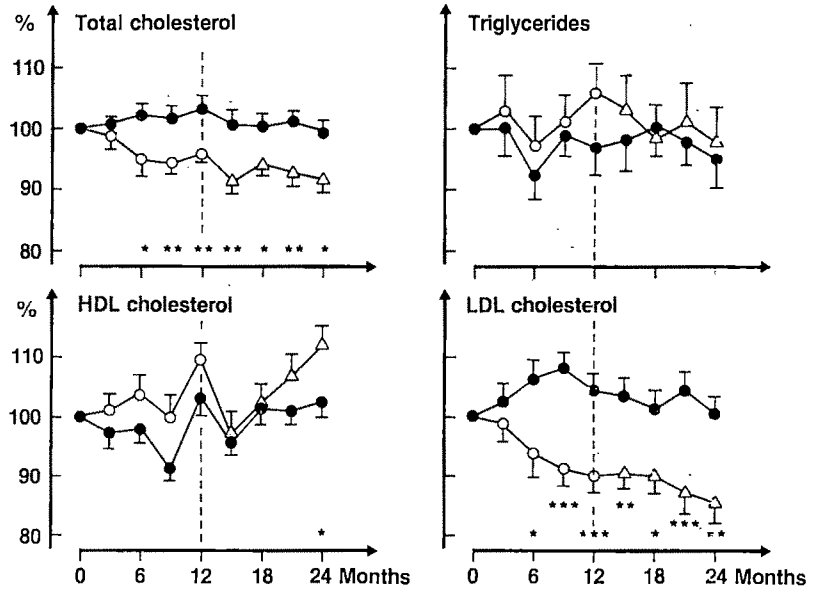

Fig. 2. Serum lipids and lipoproteins during treatment with percutaneous estrogens (○), percutaneous estrogens combined with cyclic progesterone (△), or placebo (●). Fig. 3. Cumulated treatment response on serum lipids and lipoproteins following percutaneous estrogens *(striped bar)*; percutaneous estrogens combined with cyclic progesterone *(hatched bar)*; and placebo *(open bar)*. Values are given as mean ± 1 SEM and expressed in percent of initial values. Significance of difference from the placebo group: ** $p < 0.01$, *** $p < 0.001$.

hours of administration,[13] and a large part of the estradiol is converted to estrone in the gastrointestinal tract.[13] Binding of estrone in mouse liver has been shown to be greater than that of estradiol,[14] and estrone has been found to be twice as active as estradiol on rat hepatocytes.[15] Therefore it might be hypothesized that the high estrone levels, which are a consequence of hepatic extraction after oral administration, might result in a greater stimulation of the liver. This would induce changes in lipoprotein metabolism of greater magnitude and with a shorter time course than similar doses of percutaneous estrogens, in which absorption is slow and initially bypasses the liver and in which the estradiol/estrone ratio remains within the premenopausal range.

Cyclic addition of a progestogen is recommended for postmenopausal estrogen replacement therapy, since it reduces the risk of endometrial hyperplasia[5] and neoplasia.[6] Unfortunately, some progestogens have been found to affect serum lipids adversely,[8] although these actions depend on the type and dose of the implicated progestogen, as well as on the concomitant use of estrogen.[8] In the present study, addition of 200 mg of micronized progesterone did not alter the estrogenic effect on serum lipoproteins. However, our study design does not allow us to determine whether the changes in serum lipids during the second year of treatment are caused by the continuous administration of estradiol or by the addition of progesterone. However, the findings agree with previous studies on micronized progesterone,[8] indicating that progesterone does not

influence or at least does not adversely affect lipoprotein metabolism. The dose of 200 mg of progesterone induced regular withdrawal bleedings in 70% of the hormone-treated women compared to 10% during the year with percutaneous estrogens alone. Twelve women did not experience bleeding during the estrogen monotherapy, and in five women, bleeding did not occur after the addition of progesterone. A recent study reported a similar frequency of bleeding, and 200 mg of micronized progesterone taken orally for 10 days was found to induce significant biochemical and morphologic effects on the endometrium.[16] These findings, plus the fact that progesterone was administered for 12 days in each cycle during the present study, suggest that adequate protection of the endometrium was obtained during the combined therapy.

We conclude that percutaneous administration of estrogen produces changes in total serum cholesterol and LDL cholesterol similar to those observed with oral estrogens. However, the magnitude and time course of the response seem to be modulated by the route of administration. Addition of oral micronized progesterone does not influence the beneficial actions of estrogen on serum lipids and lipoproteins and seems to be a proper "progestogen" in percutaneous estrogen therapy.

We wish to thank Laboratories Besins Iscovesco for supplying the Oestrogel cream, Utrogestan capsules, and placebo.

Use of the urinary director appliance for management of voiding problems after radical vulvectomy

Karen L. Ilika, M.D., and Patrick Duff, M.D.
Tacoma, Washington

This case report describes the use of a simple appliance for the control of the urinary stream in four patients who experienced difficulty voiding after radical vulvar surgical procedures. (Am J Obstet Gynecol 1987;156:72-3.)

Key words: Vulvectomy, urinary stream, funnel

Certain patients may experience voiding problems after radical genitourinary surgical procedures. We recently evaluated four women who complained of persistent deviation of the urinary stream after radical vulvectomy. The resulting problem was that of urine spraying out between the top of the toilet bowl and the toilet seat. To our knowledge, this phenomenon has not been previously described.

Methods

The Sani-Fem Urinary Director (Sani-Fem, Downey, California) is sold as an aid for women who backpack. Its purpose is to allow women to urinate in the standing position without disrobing. The appliance is an elliptically shaped plastic funnel measuring approximately 5 inches in its longest diameter. The elliptical opening is held against the perineum. An outflow spout located at one end of the ellipse directs the urine stream away from the user (Fig. 1). We offered this device to four patients who complained of uncontrolled spraying of urine when voiding after radical vulvar surgical procedures.

Results

The first patient to try this device was a 63-year-old woman who had undergone a radical vulvectomy for malignant melanoma 18 months before our evaluation. She underwent an anterior repair 6 months after vulvectomy because of symptoms of stress urinary incontinence. At the time of evaluation she was again having incontinence symptoms as well as difficulty in directing the urine stream. She used the funnel device while awaiting further operation. After experimenting with various positions, she found that the device worked best for her in the sitting position with the spout directed posteriorly. She subsequently underwent a suprapubic urethropexy and scar revision of the perineum, resulting in improvement of her symptoms.

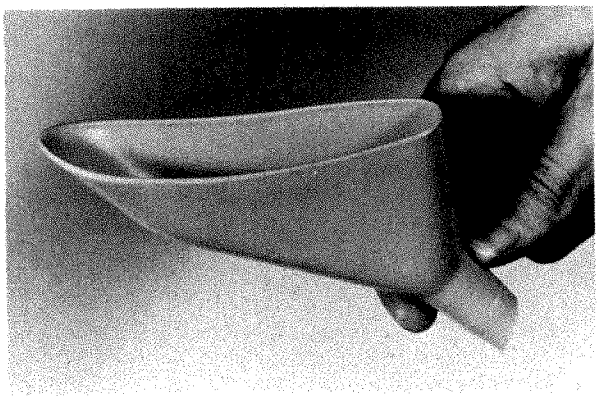

Fig. 1. The Sani-Fem Urinary Director.

Our second patient was a 61-year-old woman who began to spray urine after a radical vulvectomy and radiation therapy for squamous cell carcinoma. She described her difficulty as being intermittent and used the funnel most often when away from home. She was quite satisfied with this solution and had been using it for 18 months.

Our third and fourth patients underwent radical vulvectomy for Stage II squamous cell carcinoma of the vulva. Both patients developed the problem of spraying urine in the immediate postoperative period. One used the urinary director successfully while still in the hospital. She subsequently has had less need for it. The other patient, a 51-year-old businesswoman, tried the device and found that it contained the spray of urine well. However, she discovered that a disposable plastic bag over her hand provided an inexpensive and convenient shield that served the same purpose. For her lifestyle this innovative alternative proved to be more acceptable.

Comment

Although not previously described, the problem of postoperative spraying of urine is probably quite common after radical vulvar operation. The onset of this problem may be in the immediate postoperative period or it may be delayed. It causes a great deal of distress for certain patients. Physicians need to be aware of and inquire about its occurrence. The Sani-Fem Urinary Director is an inexpensive (approximately $9) and easily used device that avoids the need for internal instrumentation and the resultant risk of infection. In selected patients, it presents an attractive alternative to further operation. Patients who may benefit from its use should be made aware of its availability.

Liposarcoma presenting on the vulva

John J. Brooks, M.D.,* and Virginia A. LiVolsi, M.D.
Philadelphia, Pennsylvania

A myxoid liposarcoma of the vulvar perineum in a 15-year-old girl is described. The tumor recurred as a poorly differentiated round cell liposarcoma and resulted in the patient's death. Clinicians and pathologists should be aware that this tumor may rarely present on the vulva. (Am J Obstet Gynecol 1987;156:73-5.)

Key words: Vulva, sarcomas, liposarcoma

During an analysis of all of our vulvar soft tissue tumors, we encountered an exceptional case that was not originally recognized. A myxoid liposarcoma presenting on the vulva is reported. Wide local excision and postoperative radiotherapy may have been curative in this initially low-grade sarcoma. Since this lesion may mimic other soft tissue tumors, it is important that its rare occurrence on the vulva be recognized.

Case report

A 15-year-old white girl complained of a large mass in the groin, in December 1975. Physical examination disclosed a 6.5 cm protrusion on the vulvar perineum. Encroachment on the posterior vagina and anterior portion of the rectum was noted on internal examination. The initial clinical diagnosis was soft tissue sarcoma. An 18 cm tumor was completely removed at operation through an abdominoperineal approach. At first, the lesion was misdiagnosed as a cellular neurofibroma, and no further therapy was given.

Twenty months later, in August 1977, the tumor recurred as an 11 cm mass in the adjacent tissues of the left posterior medial thigh. At this time the initial tissue was reviewed and the diagnosis changed to a low-grade myxoid liposarcoma. Small, widely scattered cells were present in a myxoid-ground substance with an accompanying capillary network (Fig. 1). Only a rare mitotic figure was noted and the tumor contained no evidence of necrosis or pleomorphism. In contrast, the recurrence was a high-grade sarcoma with abundant mitoses, marked cellularity, necrosis, and nuclear pleomorphism with tumor giant cells (Fig. 2).

After the recurrence, the patient was given chemotherapy to no avail. The patient died of disease 31 months after presentation, of local disease and renal failure. There was no clinical evidence of metastatic disease at the time of death. No autopsy was performed.

Comment

Liposarcoma is one of the most common soft tissue sarcomas of adults. The majority of cases occur on the lower extremities, particularly the thigh; the retroperitoneum is also a frequent location. Although liposarcoma has been reported in unusual locations, there appear to be no reports of its presentation on the vulva, nor are there vulvar cases contained within larger series on liposarcomas. The only previous reference to this topic is that by Gompel and Silverberg,[1] who referred to a single case of liposarcoma occurring on the vulva; no clinical or pathologic details were provided.

It is debatable whether the tumor described here arose in the soft tissues of the vulva and grew inwardly to involve the pelvis or originated as a primary pelvic liposarcoma. The bulk of the tumor was found to be in the pelvis at initial operation. However, the pattern of recurrence is certainly unusual for a primary pelvic sarcoma, since recurrent disease would be expected to

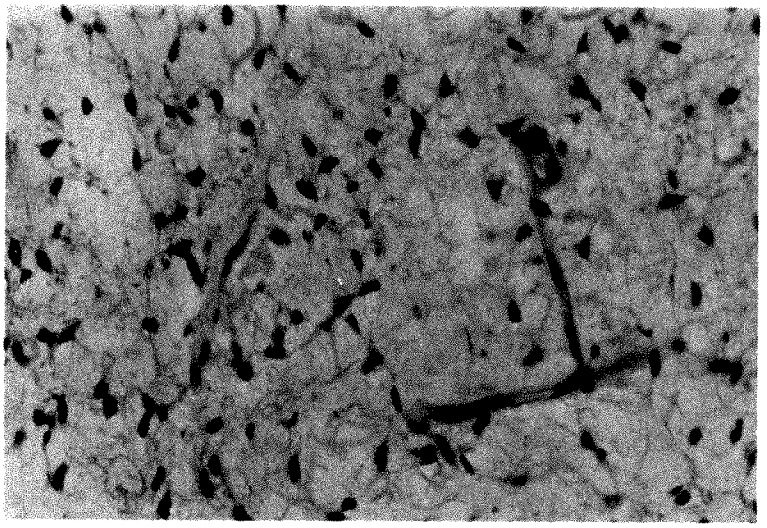

Fig. 1. Initial excision. A loose myxoid stroma with a delicate capillary network *(right)* supported uniform spindled cells with occasional vacuoles consistent with a low-grade liposarcoma.

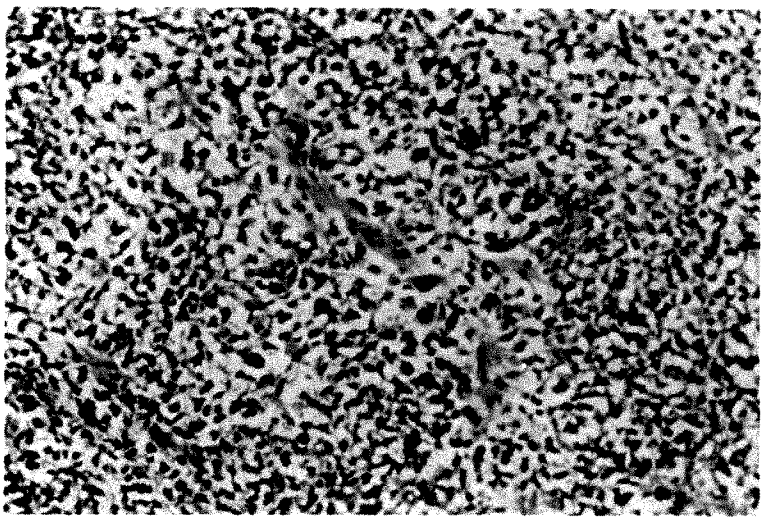

Fig. 2. Recurrence. The increased cellularity and scattered pleomorphic cells *(center)* mark this sarcoma as a high-grade round cell liposarcoma.

occur more superiorly within the retroperitoneum. In this case the tumor recurred on the left posterior medial thigh directly adjacent to the vulva. This pattern of recurrence favors the concept of a primary vulvar neoplasm.

Another unusual aspect of this case was the patient's age. Liposarcoma is a tumor of adults with a peak incidence between the fifth and seventh decades. Rare cases of childhood liposarcoma have been reported and two age peaks in the pediatric population may be seen; one at 2 years of age and the other in the early second decade (13.5 years).[2] Interestingly, there is a female predominance. The location of these pediatric tumors essentially parallels that in the adult. Seventy-six percent of the reported cases had myxoid histologic features, as in our case. In contrast to adults, children appeared to have a more favorable prognosis; the overall survival was 80% in those patients followed up for at least 18 months.[2]

Our case, apparently the first well-documented vulvar liposarcoma, was initially misdiagnosed. The low degree of cellularity, the uniform nature of the cells, and the lack of a prominent mitotic rate were misinterpreted as indicating a benign neurofibroma, a much more common vulvar tumor. However, these features as well as the prominent capillary vascular network are classic for the low-grade myxoid type of liposarcoma. One can only speculate that, had the correct diagnosis been made, radiotherapy may have prevented local recurrence and resulted in a long-term disease-free in-

terval. It is hoped that this report will call attention to the occurrence of this low-grade sarcoma on the vulva so that such confusion can be avoided in the future.

We would like to thank Dr. Arthur S. Patchefsky of Thomas Jefferson University Hospital for submitting the case in consultation with Dr. Horatio T. Enterline.

Serum CA-125 antigen levels increase during menses

Donald E. Pittaway, M.D., Ph.D., and Jamil A. Fayez, M.D.
Winston-Salem, North Carolina

Serum CA-125 antigen levels were measured by radioimmunoassay before and during menses in women with and without endometriosis. Mean CA-125 levels were significantly increased in both groups during menses. Samples obtained during menses represent a potential source of elevated levels and false positive results. (Am J Obstet Gynecol 1987;156:75-6.)

Key words: CA-125 antigen, endometriosis, menstrual cycle

CA-125 is a membrane antigen that is elevated in the serum of approximately 82% of women with epithelial ovarian carcinomas[1] and is mildly elevated in some women with endometriosis.[2] While evaluating CA-125 levels in infertile women, we observed higher levels than expected when the samples were drawn during menses. Consequently, we evaluated CA-125 levels before and during menses.

Methods

Sera from 20 infertile women in whom samples were available before (cycle days 23 to 26) and during (cycle days 2 to 4) menses were analyzed retrospectively. All women had ovulatory cycles and were not receiving infertility therapy when samples were obtained. The women were divided into a nonendometriosis group and an endometriosis group (revised American Fertility Society classification, 1985) at a subsequent laparoscopy performed as part of the infertility evaluation. The mean ages (±SEM) of the two groups were 29.5 ± 0.9 for the group without endometriosis and 29.3 ± 1.1 for the group with endometriosis and were not statistically different. The etiologies of infertility in the group without endometriosis were tubal (five women), adhesions (two women), male factor (one), and unexplained (one). CA-125 was measured in the serum with a solid phase radioimmunoassay according to the manufacturer's instructions (Abbott Laboratories, North Chicago, Illinois). A determination of the serum β-sub-

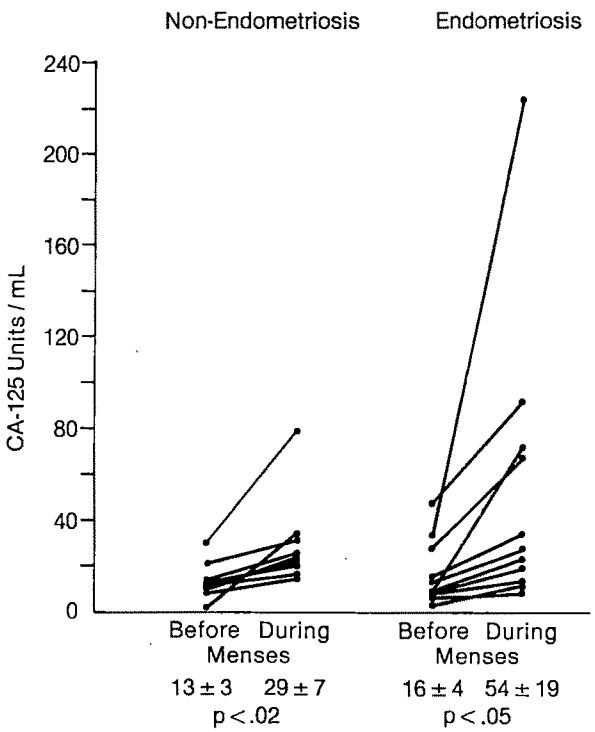

Fig. 1. Serum CA-125 levels before and during menses in women without endometriosis (n = 9) and with endometriosis (n = 11). The mean ± SEM values are indicated below each group.

unit of human chorionic gonadotropin (Clinetics Corporation, Tustin, California) was performed on each sample to exclude an occult pregnancy. The data were evaluated by paired and unpaired *t* tests.

Results

As shown in Fig. 1, the mean CA-125 levels were significantly higher during menses in both the group without endometriosis ($p < 0.02$) and the group with endometriosis ($p < 0.05$). In both groups, all CA-125 levels before menses were less than 65 U/ml. In the group without endometriosis one of nine women (11%) and in the group with endometriosis four of 11 women (36%) had CA-125 levels >65 U/ml during the menses.

Comment

In 988 nonpregnant patients attending a gynecologic clinic, 11 (1.1%) had elevated CA-125 levels (>65 U/ml).[3] Since a large proportion of these patients (n = 652) were presenting for an annual checkup and since women nearly always arrange a gynecologic visit while not menstruating unless vaginal bleeding has been a problem, most of the women in that series would not be expected to be menstruating.

In the present study of a selected group of infertile women, a higher CA-125 level was observed during menses, and five of 20 women (25%) had elevated levels (>65 U/ml) during but not before menses. An increase in CA-125 levels during menses has also been observed in rhesus monkeys with and without endometriosis.[4] We conclude that CA-125 determinations performed during the menses, particularly in women with endometriosis, represent a source of higher values and false positive results.

Advanced ultrasonic placental maturation in twin pregnancies

G. Ohel, M.D., M. Granat, M.D., D. Zeevi, M.D., A. Golan, M.D., Sh. Wexler, M.D., M. P. David, M.D., and J. G. Schenker, M.D.

Jerusalem and Tel Aviv, Israel

The mean length of twin pregnancies is shorter than that of singleton pregnancies. The possibility that the shorter gestation of twins is associated with advanced fetal maturational changes was studied in relation to placental maturation. For this purpose, the sonographically determined placental gradings of 158 twin pregnancies and 474 singleton pregnancies were compared at different gestational ages. The percent distributions of placental grades, from I to III, were significantly different throughout the third trimester, with a preponderance of Grade III placentas in the twin group ($p < 0.001$). Considering the reported association of Grade III placentas with advanced gestation as well as fetal lung maturity, the present study suggests earlier maturational changes in twin fetuses compared with singleton fetuses. (Am J Obstet Gynecol 1987;156:76-8.)

Key words: Sonographic placental maturation, twin pregnancies

Advances in ultrasonic imaging have enabled the characterization of placental restructuring throughout gestation. A grading system, from 0 to 3, has been proposed to describe placental maturational changes,[1] and these have been correlated to fetal pulmonary maturity.[1-4]

Since normal twin gestations are commonly shorter than singleton pregnancies,[5] it may be anticipated that maturational processes, including those involved in fetal lung development, occur at an earlier gestational age in twins than in singleton fetuses. The present study has attempted to investigate this possibility by compar-

ing the sonographic placental grading at different gestational ages in both twin and singleton pregnancies.

Material and methods

A retrospective analysis was carried out on records of routine real-time ultrasonic examinations of twin and singleton pregnancies. In all studied cases, the gestational ages were known through the "last menstrual period" or early ultrasound examinations. Cases were omitted when discrepancies of more than 2 weeks were noted between the clinical and sonographically determined gestational ages. Also not considered were cases with medical or obstetric complications. A total of 158 twins were studied, each with one ultrasonic examination, at gestational ages that ranged from 23 weeks to term. For each twin pregnancy, three consecutively performed ultrasound examinations of singleton pregnancies, matched for gestational age, served as controls.

Ultrasound examinations were performed with the use of linear array real-time scanners with 3.5 MHz transducers. Placental maturation was evaluated with the use of the grading classification of Grannum et al.[1] Where an equivocal grading was given, the more advanced grade was assigned to that case.

The χ^2 test was used to analyze the difference in the distribution of placental Grades I to III at the different gestational ages in the two study groups. A logistic regression analysis, with the Bio Medical Program Logistic Regression (BMDPLR) computer program, was used to demonstrate the difference between singleton and twin pregnancies with regard to the proportion of cases with Grade III placentas at the different gestational ages.

Results

The percent distribution of placental gradings, from I to III, in the twin and singleton pregnancies is shown in Table I. From 29 weeks to term the percent distribution of placental gradings showed a statistically significant difference when the two groups were compared, with a preponderance of Grade III placentas in the twin group. No differences were apparent at the earlier gestational ages of 23 to 28 weeks.

The proportion of Grade III placentas in the twin and singleton groups is shown in Fig. 1.

While the proportion of Grade III placentas was increased with advancing gestation in both groups, it was significantly greater in the twins at each gestational age group from 29 weeks to term ($p < 0.001$).

Comment

The key finding of this study is the demonstration of an advanced sonographic maturation of twin placentas as compared with singleton placentas. Grade III placentas were first noted in twins of 29 to 31 weeks' gestation, while this grade was absent in singleton pregnancies of comparable gestational ages. Thereafter, at each 3-week interval to term, Grade III placentas were significantly more common in twins compared with singletons ($p < 0.001$).

Previous studies have demonstrated that the placenta undergoes a series of progressive morphologic changes, observed by ultrasonography, and these are related to gestational age and fetal lung maturation.[1-4] That gestational age is not the only determinant of placental grading is well illustrated by our finding of a more advanced placental maturation in twins compared with singletons of similar gestational ages. This may point to a difference in the rate of maturation dynamics of twins and singletons. In this respect our findings are in accord with, and complementary to, a recent study of the amniotic fluid lecithin/sphingomyelin ratio, which demonstrated fetal lung maturation to occur several weeks earlier in twins compared with singletons.[6] A possible explanation of the observed differences in placental maturation may be related to the different intrauterine growth pattern of singleton and twin fetuses.[7] The altered growth potential of twins may parallel the situation of growth retardation in singleton fetuses. It has been suggested that intrauterine growth is an important determinant of sonographically diagnosed placental maturity and that for the small fetus a mature (Grade III) placeta is significantly associated with growth retardation.[8]

In the case of singleton pregnancies, it is very unlikely for a neonate to develop hyaline membrane disease in the presence of a Grade III placenta near term.[1-4] Nevertheless, this view is not shared by all, and one report has concluded that placental grading is not accurate enough to replace amniocentesis as the standard test of fetal pulmonary maturity.[9] As the presence of a Grade III placenta is affected by both gestational age and pregnancy complications,[8, 10] at least in a subgroup of preterm complicated pregnancies, sonographic grading of the placenta as Grade III may still be associated with hyaline membrane disease.[10] With this in mind and until data that correlate placental grading of twins with hyaline membrane disease become available, it would seem unjustified in twin pregnancies to rely solely on placental grading as an indicator of fetal pulmonary maturity.

We thank Mr. Israel Einot of the statistical consultation service at the Hebrew University, Mount Scopus, Jerusalem, Israel.

Antenatal sonography of fetal malformations associated with drugs and chemicals: A guide

Gideon Koren, M.D., A.B.M.T., Michelle Brille Edwards, M.D., and Murray Miskin, M.D.
Toronto, Ontario, Canada

A guide presented in this article provides the sonographer with a list of fetal malformations that have been described in association with specific drugs or chemicals and that can be visualized by current ultrasonographic techniques. (AM J OBSTET GYNECOL 1987;156:79-85.)

Key words: Ultrasonography, fetal malformations, teratogens

Since the thalidomide disaster in the 1950s, an increasing number of drugs and chemicals have been incriminated as causing teratogenicity or fetal toxicity. As the majority of pregnant women are exposed to at least one medication during pregnancy either before or after realizing they are pregnant,[1] the need to determine the relative risk that a certain agent will cause malformations is of utmost importance.

Data on chemically induced teratogenic risk are derived from animal studies, human case reports, or epidemiologic studies. While such information is essential for assigning a relative risk to a potential teratogen, it may be of little help for medication in a specific case. Sonography has emerged as a powerful tool for antenatal detection of fetal anomalies. It is conceivable therefore that more and more pregnant women exposed to drugs and chemicals will be referred for diagnosis of or to rule out malformations associated with these agents. Currently, pregnant women who attend our Motherisk Clinic for antenatal counseling of drug-chemical exposure are scheduled for a level 2 sonographic evaluation at 17 to 18 weeks of gestation.

The guide aims at providing the sonographer with a practical list of malformations that have been described in association with specific drugs or chemicals.

Methodologic considerations

Two groups of agents are included. (1) Common drugs and chemicals that have been associated with malformations are listed. In many cases the incriminating data are controversial; hence the inclusion of a certain malformation in this guide by no means suggests that we are convinced that the agent is a teratogen. Because of the heterogeneity of the data, the source of information is mentioned (for instance, case reports, retrospective or prospective studies). (2) Drugs and chemicals that have been proved beyond doubt as teratogens are listed.

Table I (see pages 80-85) includes only malformations that can be visualized by current ultrasonographic techniques and cannot be used as a complete list of drug-induced teratogenicity. The data in this guide have been extracted from currently available literature.[1-6]

Certain points with respect to the ultrasound examination itself should be stressed. It is probably best carried out by a physician ultrasonographer who has had significant experience in looking at fetuses. A very meticulous technique and high-resolution real-time equipment should be used. The examination is best recorded on videotape so that it can be reviewed as needed. A great deal of patience is required in this type of study, especially when one is examining the face, digits, and heart. At the outset of the examination it should be explained to the patient that the examination may take some time to complete and that more than one sitting may be required.

Fryns syndrome: A predictable, lethal pattern of multiple congenital anomalies

Arnon Samueloff, M.D., Daniel Navot, M.D., Arie Birkenfeld, M.D., and Joseph G. Schenker, M.D.
Jerusalem, Israel

Fryns syndrome is a unique pattern of lethal multiple congenital malformations with variable expression. A family in which all four sibs conformed to Fryns syndrome is detailed and substantiates the criteria for definition of the syndrome; perinatal mortality, hypoplastic lungs, and facial deformities should be highly suggestive of the syndrome. The addition of a strong family history, diaphragmatic hernias, distal limb deformities, and early onset of polyhydramnios with subsequent premature delivery should definitely confirm the diagnosis. (Am J Obstet Gynecol 1987;156:86-8.)

Key words: Fryns syndrome, multiple congenital anomalies, hypoplastic lungs, distal limb malformation, facial deformities

Recently a new lethal autosomal recessive syndrome of multiple congenital anomalies, with familial occurrence, has been defined.[1-3] In 1979, Fryns et al.[1] reported an instance of two female sibs with a unique malformation pattern including multiple facial anomalies, diaphragmatic defects, hypoplastic lungs, and distal limb deformities. Later the same group added an additional case with a similar pattern.[2] Lubinsky et al.[3] contributed two additional cases and termed the malformation pattern Fryns syndrome. Recently we encountered a family in which all four sibs conformed to Fryns syndrome, the last of which was diagnosed in utero.

The four additional cases of Fryns syndrome are reported in order to further delineate the variability within the syndrome. The extended series establishes a malformation pattern that, together with the strong family history, should alert the perinatologist for a possible recurrence.

Family history

The parents were healthy, unrelated Sepharadic Jews, aged 31 and 28 years. The mother had had five pregnancies; in one, spontaneous abortion occurred during the first trimester, while four pregnancies advanced into the third trimester of gestation. All four were complicated by the early onset of polyhydramnios and terminated in premature deliveries of three boys and a girl who had the major characteristicis of Fryns syndrome and died shortly after birth. Table I details pregnancy and delivery characteristics of the four siblings, as well as major anomalies according to the systems affected. The four most consistent findings are polyhydramnios, facial deformities, diaphragmatic hernia, and hypoplastic lungs.

Prior to the last pregnancy, a search for possible etiologic factors of the recurrent malformation pattern was performed: glucose tolerance test, Sabin-Feldman test, karyotyping of both parents, VDRL test, and anticytomegalovirus antibodies gave no clue as to a possible cause. The last pregnancy was uneventful until the twenty-sixth week, when rapidly advancing polyhydramnios was detected. The volume of amniotic fluid stabilized toward the twenty-ninth week, after repeated amniocenteses. Ultrasonography revealed sonolucent areas adjacent to the fetal heart, a picture consistent with dilated loops of bowel inside the thoracic cavity. In the thirty-first week of gestation, after premature rupture of the membranes and in view of a previous cesarean section, a repeat cesarean section was performed. A 2000 gm female infant with multiple congenital anomalies was delivered (Fig. 1, *A* and *B*). The infant died within a few minutes after delivery. Autopsy revealed multiple facial defects, agenesis of the diaphragm, bilaterally atrophic kidneys, distal limb deformities, and some other anomalies detailed in Table I.

Comment

Up to now, five cases of Fryns syndrome have been reported in the literature; the present series adds four additional cases. The marked variability within the syndrome necessitates the description of each and every affected fetus until final criteria are set up for definition

of the syndrome. We have compiled in Table I all the malformations encountered in the nine reported cases, as well as pregnancy and delivery characteristics. Cases Nos. 3, 6, and 9 conform to the original pattern described by Fryns et al.[1] (Cases 1 and 2). Our two additional cases (Nos. 7 and 8) are concordant in the early onset of polyhydramnios, premature delivery, and the presence of diaphragmatic hernias and hypoplastic lungs. Some of the missing features, such as distal limb deformities, may be attributed to the scarcity of information available for those two cases. The pattern of multiple congenital anomalies in the extended series still conforms to the syndrome originally described by Fryns et al.[1] Table II details the concordant features in

Table II. Concordant features in nine cases of Fryns syndrome

Feature	*No. of cases*
Perinatal mortality	9
Lung hypoplasia	9
Facial deformations	9
Family history	8
Diaphragmatic defects	8
Distal limb hypoplasia	7
Early onset of polyhydramnios	7
Premature delivery	7
Genital anomalies	6
Hypoplastic nipples	4
Cloudy cornea	3
Small thorax	3

the nine cases. The uniformly reported perinatal mortality, hypoplastic lungs, and facial deformities should be highly suggestive of Fryns syndrome. A strong family history, diaphragmatic hernias, distal limb deformities, and early onset of polyhydramnios with subsequent premature delivery should probably be added as minimal criteria for the definition of the syndrome (Table II).

The information now available should suffice for the prediction of the syndrome in future sibs. A thorough prenatal evaluation by ultrasonography, with or without amniography, may detect the polyhydramnios, diaphragmatic hernia, hypoplastic lungs, renal anomalies, and distal limb anomalies. A positive prenatal diagnosis may influence clinical decision making as to the route and timing of delivery.

Unruptured pregnancy in a heterotopic fallopian tube: Evidence for transperitoneal sperm migration

Charles Brown, M.D., William E. LaVigne, M.D., and Santiago L. Padilla, M.D.
Augusta, Georgia

A case of an unruptured pregnancy in a heterotopic left fallopian tube isolated from a unicornuate uterus with a normal contralateral tube and ovary is presented. The corpus luteum of pregnancy was in the left ovary. This case provides supportive evidence for transperitoneal sperm migration. (Am J Obstet Gynecol 1987;156:88-90.)

Key words: Ectopic pregnancy, müllerian anomaly, sperm migration

Congenital anomalies of the müllerian ducts have been estimated to occur in 1 in 500 to 1 in 2000 women.[1] The most common are the uterine anomalies. Structural anomalies of the fallopian tubes are very rare. Anomalies reported include complete absence of the tube and ovary, unilateral müllerian duct development (uterus unicornis), maldevelopment together with failure of fusion of the ducts, duplication of the tube, and absence of tubal segments. Ectopic pregnancy in heterotopic fallopian tubes is extremely rare.[1, 2]

A case of an unruptured pregnancy in a heterotopic fallopian tube associated with a unicornuate uterus is presented. It provides evidence for the phenomenon of transperitoneal sperm migration.

Case presentation

A 24-year-old primigravid woman presented at 7 weeks' menstrual age with mild vaginal bleeding. She had had a positive human chorionic gonadotropin radioreceptor assay approximately 2 weeks earlier. On examination, the abdomen was soft and there was a small amount of bright red blood in the vaginal vault. Bimanual examination revealed a slightly enlarged uterus and no palpable adnexal masses. Three days later she had continued bleeding without abdominal pain and complained of having passed some tissue from the vagina. Physical examination was essentially un-

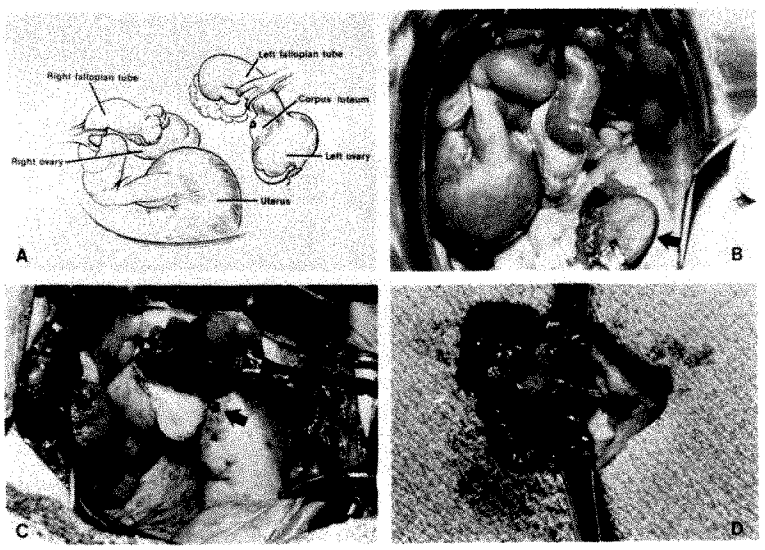

Fig. 1. *A*, Diagram of intraoperative findings. *B*, The unicornuate uterus with a normal right fallopian tube and ovary. Part of the heterotopic left fallopian tube is seen *(arrow)*. *C*, Heterotopic fallopian tube with a corpus luteum *(arrow)*. *D*, A small gestational sac in the ampulla of the heterotopic tube.

changed except for increased tenderness of the uterus and adnexa. An ultrasound examination revealed an empty uterus, a left-sided complex mass posterior to the uterus, and fluid in the cul-de-sac. A serum titer of the β-subunit of human chorionic gonadotropin was 147 mIU/ml. A culdocentesis produced 22 ml of bright red nonclotting blood.

The patient's past medical history was significant for having had a left inguinal hernia repaired 6 months before admission.

At laparotomy, a slightly enlarged hemiuterus was noted (Fig. 1). The right fallopian tube, round ligament, broad ligament, and ovary appeared to be normal. A heterotopic left fallopian tube and ovary were found attached to the pelvic sidewall. This fallopian tube was 4 to 5 cm in length and consisted of an ampulla and a well-developed fimbriated end. The ampulla was distended and active bleeding from the fimbriated end was noted. Careful exploration failed to disclose any connection between the heterotopic fallopian tube and the uterus. The left fallopian tube was resected and the left ovary, which contained the corpus luteum, was left intact. The tube was opened and it contained a gestational sac. Microscopic examination of the tube revealed a hematosalpinx and ghost villi. Several multinucleated cells typical of syncytiotrophoblast were seen. The postoperative course was essentially uneventful. A postoperative pyelogram showed absence of the left kidney and collecting system.

Comment

Our case is unique because the heterotopic fallopian tube that contained the ectopic pregnancy was located at the pelvic brim and was associated with a unicornuate uterus. There also was absence of rudimentary horns and broad or round ligaments on the side of the heterotopic tube. Dabby and Nardone[1] reported a ruptured ectopic pregnancy in a fallopian tube found lateral to the ascending colon. The uterus was supposedly normal and the position of the ovary was not clear. Szlachter and Weiss[2] reported unilateral, segmental absence of a tube that contained an ectopic pregnancy associated with a bicornuate uterus.

This case illustrates interesting anatomic and physiologic features of the female genital tract. In addition, it demonstrates the phenomenon of transperitoneal migration of sperm. For pregnancy to have occurred in the heterotopic left fallopian tube, sperm must have traversed the uterus and the right tube and crossed the peritoneal cavity.

The association of uterus unicornis and agenesis of the contralateral kidney has been documented. In considering malformations of the female reproductive system one must appreciate their frequent association with defects of the urologic system. This relationship is easy to understand when one considers that embryologically the urinary and genital tracts have extremely close origins. At the sixth week of development the müllerian cleft appears between the lateral and the medial or gonadal portion of the urogenital ridge. The subsequent development of the müllerian system is closely related to the wolffian system. Major urinary tract anomalies have been found in a significant number of patients with imperfect müllerian duct development and vice versa. The importance of evaluating the urinary tract when clinicians encounter müllerian anomalies is emphasized.

A hysterogram should be obtained in these patients to identify any intrauterine anomalies. Hysterography was not performed in this patient because she conceived

before further evaluation. This pregnancy, however, recently ended with an intrauterine fetal death of unknown cause at 30 weeks' gestation.

In summary, this case demonstrates an unusual congenital anomaly consisting of a unicornuate uterus with a heterotopic left fallopian tube and a normal right tube and ovary. The left tube was not connected to the uterus and was attached to the left ovary by the fimbria ovarica. This tube contained an unruptured ectopic pregnancy, which provides supportive evidence for the phenomenon of transperitoneal sperm migration. The left kidney and collecting system failed to develop, emphasizing the importance of evaluating the urinary tract when müllerian anomalies are encountered.

Laparoscopy—A diagnostic aid in cases of suspected appendicitis

Its use in women of reproductive age

Nick M. Spirtos, M.D., Scott M. Eisenkop, M.D., Tanya W. Spirtos, M.D., Raymond I. Poliakin, M.D., and Lester T. Hibbard, M.D.

Los Angeles, California

In women of reproductive age the usefulness of laparoscopy in diagnosing acute appendicitis was evaluated. Eighty-six women underwent diagnostic laparoscopy. There was complete visualization of the appendix in 93% of the patients. Twenty-two patients were spared laparotomy. In the nonpregnant patients, salpingitis was the disease most often confused with appendicitis. Eighty-five percent of the patients with salpingitis had the onset of symptoms within 14 days of the last menstrual period, whereas acute appendicitis was found in 86% of the patients with the onset of symptoms >14 days after the last menstrual period. The onset of symptoms relative to the first day of the last menstrual period differed in these two groups of patients ($p < 0.01$). Patients who were spared unnecessary laparotomy had significantly diminished hospital stays ($p < 0.001$). Laparoscopy was found to be a safe and effective way to diagnose acute appendicitis in women of reproductive age, and its liberal use is recommended. (Am J Obstet Gynecol 1987;156:90-4.)

Key words: Pregnancy, ectopic, laparoscopy

Acute appendicitis is one of the few surgical diseases encountered in which a correct preoperative diagnosis is not mandatory. Negative laparotomy rates (the percentage of laparotomies resulting in the removal of a normal appendix) average 15% to 20% and are considered acceptable.[1-3] However, in women of reproductive age the negative laparotomy rate approaches 40%.[3-6] The differential diagnosis between inflammatory disorders of the female genital tract, appendicitis, torsion of adnexal structures, and other conditions remains a challenge. In addition, removal of a normal appendix is not without risk; complications include wound infection, pneumonia, peritonitis, pelvic abscess, paralytic ileus, bowel obstruction, deep vein thrombosis, infertility, and death.[7-10] Recent reports suggest that laparoscopy can significantly reduce the negative laparotomy rate associated with the diagnosis and treatment of acute appendicitis.[11, 12] This study reports the experience of the gynecology service at Los Angeles County–University of Southern California Medical Center in the use of laparoscopy for diagnosis in cases of suspected appendicitis.

From the Department of Obstetrics and Gynecology, University of Southern California School of Medicine, Women's Hospital, Los Angeles County–University of Southern California Medical Center.

Received for publication February 21, 1986; revised July 22, 1986; accepted August 14, 1986.

Reprint requests: Nick M. Spirtos, M.D., Department of Gynecology and Obstetrics, Stanford University School of Medicine, Stanford, CA 94305-5317.

Material and methods

Ninety-four women underwent laparoscopy to rule out appendicitis at Los Angeles County–University of Southern California Medical Center from 1974 to 1983. A two-puncture technique performed by resident and/or staff physicians was used. (Thirteen of the 94 patients were pregnant in the first trimester.) Eighty-six charts were reviewed for menstrual and contraceptive history as well as chief complaints, physical findings, and laboratory analysis. Eight charts were unavailable for review. All microscopic specimens were reviewed by one of us. (Statistical comparison was done with use of χ^2, Student's t test and Rankit analysis.)

Results

Eighty-six women between 16 and 42 years of age, with a median age of 21 years, presented with a chief complaint of abdominal pain. The differential diagnoses included appendicitis, salpingitis, pyelonephritis, torsion of the adnexa, ectopic pregnancy, and early intrauterine pregnancy complicated by acute appendicitis. Previously, because the diagnosis of appendicitis was considered, laparotomy would have been performed in all of these patients. Instead, laparoscopy was performed initially followed by laparotomy if indicated. Of the 86 patients, 80 had satisfactory laparoscopy (93%) in that visualization of the pelvic viscera and the entire appendix was possible.

Six laparoscopies were unsatisfactory; in these six patients the appendix could not be entirely visualized. In four instances the appendix could not be visualized because of the presence of pus and dense adhesions from ruptured appendices. In one instance the appendix could not be visualized because of the presence of a 200 ml spillage from a ruptured endometrioma. In the final instance the surgeon could not induce a pneumoperitoneum.

Of the 80 patients with satisfactory laparoscopy, 56 were thought to have acute appendicitis, 17 salpingitis, one a ruptured corpus luteum cyst, one a fecalith, and five were thought to have no pathologic condition present (Table I). Appendicitis was confirmed histologically in 51 patients; 47 correctly diagnosed at the time of laparoscopy and four diagnosed at the time of laparotomy following unsatisfactory laparoscopy. The nine patients whose diagnosis of appendicitis was incorrect at the time of laparoscopy were retrospectively diagnosed as having salpingitis, based on concurrent findings of both an inflammatory exudate on the fallopian tubes as well as the appendix and a histologic diagnosis of periappendicitis. Seventeen patients had a correct diagnosis of salpingitis at the time of laparoscopy as well as another 10 patients following laparotomy. These patients included the nine patients with salpingitis and concurrent periappendicitis and one patient who underwent laparotomy when the surgeon could not induce a pneumoperitoneum (Table I). Of the five patients who were thought to be disease-free at the time of laparoscopy, only one underwent laparotomy. Based on this patient's history, findings at exploratory laparotomy, and histologic review, a diagnosis of mesenteric adenitis was made. One patient had a ruptured corpus luteum cyst. Another patient was found to have a dilated appendix with multiple large fecaliths, and a final patient had a ruptured endometrioma.

Twenty-two patients underwent successful laparoscopy with visualization of the entire appendix and pelvic viscera, and laparotomy was avoided by confirmation of a nonsurgical diagnosis. Seventeen of these patients were found to have acute salpingitis. One patient was noted to have a ruptured corpus luteum cyst, and in four instances, no findings requiring laparotomy could be found at laparoscopy (Table I). All left the hospital with resolution of their physical findings and symptoms, and none later required surgical intervention.

The clinical presentations of the nonpregnant patients were remarkably similar. As in other series, salpingitis was the condition most often confused with

Table I. Laparoscopic and final diagnoses

	Laparoscopic diagnosis (n)	*Final diagnosis (n)*
Acute appendicitis	56	51
Salpingitis	17	27
Ruptured corpus luteum cyst	1	1
Mesenteric addenitis	0	1
Ruptured endometrium	1	1
Fecalith	1	1
No pathologic findings	5	4
Unsatisfactory	5*	0
Total	86	86

*Four patients had unsatisfactory laparoscopy with appendicitis; one patient had failed laparoscopy.

Table II. Presenting clinical data (nonpregnant patients)

	Patients with appendicitis	*Patients with salpingitis*
Median age (yr)	21	22
Range	16-42	(15-36)
Nausea and vomiting (%)	80	72

*Dates of last menstrual period not available for two patients.

appendicitis.[4,5] There was no remarkable physical finding, symptom, or laboratory test that proved to be of value in differentiating acute appendicitis from salpingitis. The percentage of patients in each group found to have a history of significant nausea and vomiting, anorexia, or obstipation for >24 hours was calculated (Table II). There was no significant difference between the salpingitis and appendicitis groups. The median age of the patients with appendicitis and salpingitis was 21 and 22 years old, respectively. The groups were remarkably similar in terms of menstrual patterns and contraception (Table III). Only when the onset of symptoms was compared to the first day of the last menstrual period did the two groups significantly differ; the patients with acute appendicitis were distributed equally throughout the menstrual cycle whereas most patients with salpingitis (85%) had their symptoms begin within 2 weeks of the last menstrual period ($p < 0.01$). Patients with the onset of symptoms at >14 days after the last menstrual period had acute appendicitis 86% of the time (Table IV).

Thirteen patients had positive pregnancy tests and were in their first trimester. In addition to menstrual histories significant for amenorrhea, the histories and physical findings of the pregnant patients in this series were similar to the nonpregnant patients. All 13 appendices were visualized; 12 were found to be acutely inflamed and one was normal. There were no maternal complications in this group and no fetal losses occurred.

Table V. Length of hospitalization

Procedure	*No. of patients*	*Hospital days*	*Significance*
Laparoscopy only	21	3.8 ± 2.5	$p < 0.001$
Laparoscopy-laparotomy with removal of normal appendix	14	5.7 ± 2.6	NS
Laparoscopy-laparotomy with removal of inflamed appendix	51	6.2 ± 3.3	

Table VI. Complications

Complications		
Type	*n*	*Final diagnosis*
Appendectomy		
Wound infections	4	Appendicitis (3); normal appendix (1)
Pelvic abscess	2	Appendicitis
Pulmonary embolism	1	Appendicitis
Ileus	1	Appendicitis
Laparoscopy		
None		

The patients with histologic confirmation of appendicitis had an average hospital stay of 6.2 ± 3.3 days (Table V). This is identical to the group of patients who underwent diagnostic laparoscopy and appendectomy with the removal of a normal appendix (5.7 ± 2.6 days). However, in those patients where laparoscopy prevented laparotomy, the average hospital stay was 3.8 ± 2.5 days, a significant decrease in hospitalization ($p < 0.001$). There were no complications among the patients spared laparotomy, but eight complications occurred in patients who required laparotomy (Table VI). It should be noted that seven of these eight patients did have acute appendicitis and needed laparotomy. There were no deaths in either group.

Comment

Recently three studies reported the use of laparoscopy in the diagnosis of acute appendicitis.[9,11,12] In 1979 the retrospective study of Leape and Ramenofsky[12] included 32 pediatric patients, the negative laparotomy rate was 12%, and six patients were spared laparotomy. There was one false negative laparoscopy. This patient developed increasingly severe peritoneal signs; appendectomy was performed and appendicitis was confirmed histologically. In 1982 Deutsch et al.[11] prospectively performed laparoscopy on 36 patients between 18 and 50 years of age. The negative laparotomy rate

was 4%, and 12 patients (33%) were spared laparotomy. There were no false-negative laparoscopies in this study. Leape and Deutsch were able to significantly reduce their negative laparotomy rates by using laparoscopy as a diagnostic aid.

In 1980 Jersky et al.[9] prospectively performed laparoscopy on 27 patients. After classification of patients into three groups (likely to have appendicitis, unlikely to have appendicitis, and uncertain), appendectomy was performed. Nineteen of the 27 patients were classified as unlikely to have appendicitis or had uncertain diagnoses. Twelve of these 19 patients had acute appendicitis, and thus Jersky et al. concluded laparoscopy would not improve their negative laparotomy rate. These results are so different from the above-mentioned studies, as well as our own, that further discussion is warranted. Although Jersky et al. classified patients as having an uncertain diagnosis if (1) the appendix was incompletely visualized (eight patients), (2) the appendix was normal and no other pathologic condition was identified (three patients), or (3) the appendix and other pelvic organs were concurrently inflamed (two patients), they did not state why the appendices were incompletely visualized or why patients with no evident pathologic condition were categorized into the uncertain group, and they did not describe what they considered coexistent salpingitis and appendicitis. Since this information is not provided, we feel it is not possible to evaluate Jersky et al.'s study and compare it to the results of others.

Unlike Jersky et al., who were unable to entirely visualize eight of 27 appendices (33%), we had little difficulty visualizing the appendix. Eighty of 86 patients (93%), including 13 pregnant patients, had appendices that were entirely visualized. Other than our one technical failure, all patients whose appendices could not be visualized ultimately proved to have surgical conditions; four had acute appendicitis, and one had a ruptured endometrioma. The diagnositc problems we encountered when the entire appendix was completely visualized were decisions regarding which organ was primarily affected when there was concurrent salpingitis and periappendicitis. In nine such patients, a review of the operative reports revealed that, in spite of the presence of gross pus exuding from inflamed fallopian tubes, a concerned surgeon decided to perform an appendectomy. The nine patients had only periappendicitis. Jersky et al. had two somewhat similar patients, and both of their patients had acute appendicitis. Thus it is somewhat difficult to wholeheartedly advocate abandoning appendectomy in such cases. In spite of the misdiagnosis in nine such cases, we were still able to halve our negative laparotomy rate by adding laparoscopy to our diagnostic armamentarium. In all, 22 patients were spared laparotomy. Perhaps as more data are gathered and more experience gained with use of laparoscopy as a diagnostic aid, laparotomy in similar cases will be avoided.

Another group of patients who presented special diagnostic problems were those presenting with lower abdominal pain, questionable uterine enlargement and a positive pregnancy test. Differential diagnoses included ectopic pregnancy, early intrauterine pregnancy with appendicitis or torsion of an adnexal structure, pyelonephritis, or a rupture of a corpus luteum cyst. Physical examinations in these patients were usually unproductive, since abdominal guarding often prevented an accurate assessment of uterine size and the adnexal structures. A correct diagnosis in this group of patients is critical because complications following a misdiagnosis include maternal and fetal death.[13, 14] Since we had only 13 pregnant patients in our study and all were in the first trimester, it is difficult to advocate laparoscopy in all pregnant patients. However, with the use of open laparoscopy, even patients with advanced gestations could undergo laparoscopy.

Other benefits of laparoscopy include decreased postoperative complications, shortened hospital stays, and a better selection of abdominal incisions. In the literature, 15% of patients whose normal appendix is removed by laparotomy develop significant postoperative complications such as pneumonia, intestinal obstruction, stress ulceration, ileus, peritonitis, pelvic abscess, deep vein thrombosis, wound infection, and death.[2, 7-9, 15] In addition, pregnant patients have an increased risk of spontaneous abortion. On the other hand, laparoscopy is associated with 1% to 2% postoperative complications.[7, 16] Laparoscopy reduces the length of hospital stay and provides the surgeon with information that can be used in selecting the location of the abdominal incision when laparotomy proves necessary. If acute appendicitis is diagnosed, a muscle-splitting incision can be made in the best location. A properly placed incision is particularly important in the pregnant patient in whom exposure can be especially troublesome.

Not only is laparoscopy in experienced hands usually safe and simple, but as a diagnostic procedure, it has proved to be quite valuable. In our series of 86 patients, the negative laparotomy rate was 19%; if laparoscopy had not been performed, the negative laparotomy rate would have been 41%. Therefore we recommend laparoscopy to rule out appendicitis in women of reproductive age. When the onset of symptoms is ≤14 days after the last menstrual period, laparotomy can often be avoided. With patients whose symptoms begin after 14 days from the last menstrual period, use of laparotomy, without laparoscopy, cannot be criticized. Since

some groups using laparoscopy have been able to decrease their negative laparotomy rate to as low as 5%, we still recommend laparoscopy in these patients. In the pregnant patient, laparoscopy also proved a valuable diagnostic aid, and we recommend its liberal use to further reduce negative laparotomy rates. Only when the entire appendix is visualized should laparoscopy be called satisfactory.

In summary, although these data were collected and analyzed retrospectively, valuable clinical information was acquired. First, it is apparent that, with experienced laparoscopists, adequate visualization of the appendix is possible in most patients (93%). In those patients where visualization was not adequate, significant pathologic conditions requiring laparotomy proved to be the reason visualization was not possible. Second, our institution's negative laparotomy rate was significantly reduced from 41% to 19% by use of laparoscopy. This study was not prospectively designed, but there are historic controls that have consistently documented negative laparotomy rates of 40% for women in the reproductive age group. This, as it happens, is almost identical to what ours would have been if laparoscopy had not been performed on our patients. Although there is some selection bias on our study population, it is difficult to conclude that we are overstating the benefit of laparoscopy in the differential diagnosis of appendicitis from salpingitis. Third, it is interesting to note that, as suspected, salpingitis develops much more commonly early in the menstrual cycle. In fact, only four of 29 (13%) of the patients with the onset of symptoms more than 14 days after the last menstrual period had salpingitis. With the above guidelines and use of the laparoscope, surgeons and obstetricians-gynecologists should be able to significantly reduce negative laparotomy rates in diagnosing women with suspected appendicitis.

GYNECOLOGY CONTINUING MEDICAL EDUCATION
Las Vegas, Nevada

For 1987. . .
Three **weekend** programs designed to update and maximize **your** Continuing Professional Development!

- ☐ **Outstanding Faculty**. . . acknowledged authorities in their fields
- ☐ **Registration is easy**. . . use Visa, MasterCard and/or our convenient 800 number **1-800-NEV-OBGY — $375.00 for physicians and $200.00 for nurses**
- ☐ **Economical**. . . Take advantage of our three seminar package. Pay full registration fee for any two 1987 seminars and get the third one ***FREE.***
- ☐ **Relaxed atmosphere**. . . at the lovely Frontier Hotel on the Las Vegas Strip, adjacent to the fabulous Fashion Show Mall
- ☐ **"Take home messages"**. . . in syllabus provided at each seminar
- ☐ **Time available for one-on-one**. . . There's plenty of time for participant/faculty interaction!
- ☐ **Convenient Times!**. . . Two half-day sessions on a weekend. Minimizes time away from your practice. No Marathon sessions!
- ☐ **Money Back Guarantee**. . . if not satisfied

COMMON PROBLEMS IN AMBULATORY GYNECOLOGY, FEB. 7 and 8, 1987

lighlights: Transdermal Estrogens - a new approach to Menopause; Vulva/Vaginal Diseases - Where are they oing?; Periodic Screening for the GYN patient; Office Management for Urologic Problems; Outpatient Laser urgery for Infertility, & more!

aculty: William Droegemueller, M.D., Department of OB/GYN University of North Carolina; Thomas Lebherz, 1.D., Department of OB/GYN, UCLA School of Medicine; William Keye, Jr., M.D., Department of OB/GYN, Iniversity of Utah School of Medicine

REPRODUCTIVE ENDOCRINOLOGY IN THE OFFICE, SEPT. 26 and 27, 1987

lighlights: Update in Contraception; Amenorrhea and Athletics; PMS; Ovulation Induction; & more!

aculty: Daniel Mishell, M.D., Professor and Chairman, Department of OB/GYN, University of Southern Califor-ia; Richard Worley, M.D., Associate Professor and Associate Chairman, Department OB/GYN, University of Jtah, School of Medicine; Isaac Schiff, M.D., Associate Professor of Obstetrics and Gynecology, Department f OB/GYN, Brigham and Women's Hospital, Harvard Medical School.

CURRENT PROBLEMS IN OBSTETRICS, NOVEMBER 14 and 15, 1987

lighlights: Antenatal Diagnosis & Treatment 1987; The Cord Blood Gas, Your Friend in Court; Pregnancy and nvironmental Teratogens; Hepatitis in Pregnancy; and more!

aculty: Martin Pernoll, M.D., Chairman, Department of OB/GYN, Tulane University; Paul Summers, M.D., ssistant Professor, Department of OB/GYN, Tulane University

EGISTER NOW! The two-day seminars are $375.00 for physicians and $200.00 for nurses. Take advantage of our three seminar ackage — Pay full registration fee for any two 1987 seminars and get the third one ***FREE.*** The fee includes pen and syllabus material ach seminar), and breakfast buffet served at 7:00 a.m. each day. Refund Policy: Refund of registration fee, excluding a $25.00 ad-inistration fee will be made for cancellations made 10 days prior each seminar.

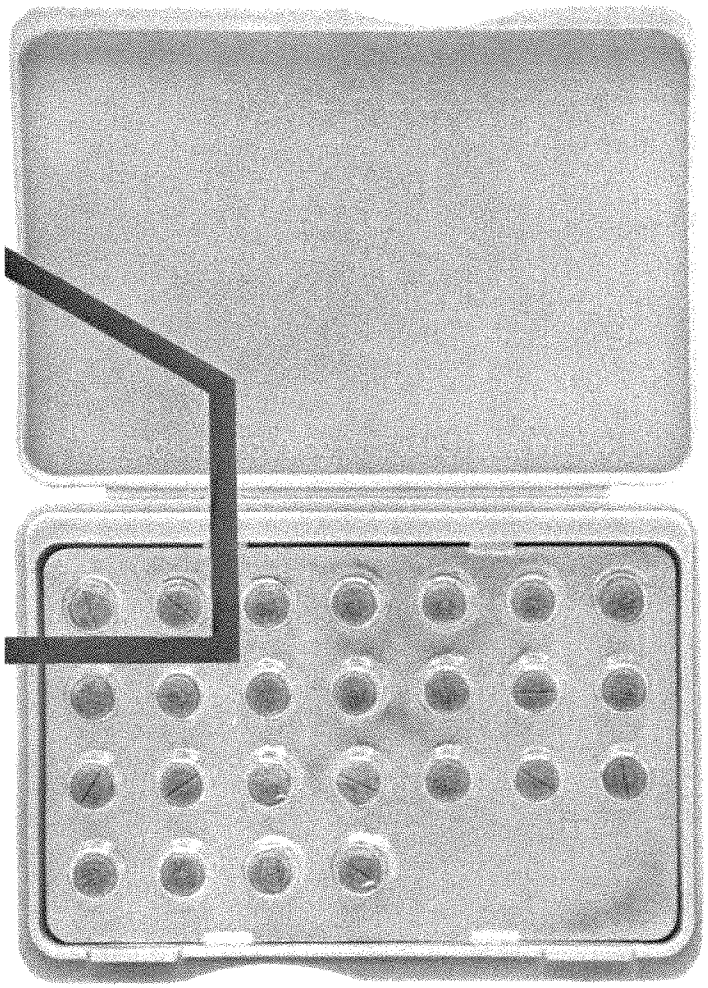
THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL— 17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

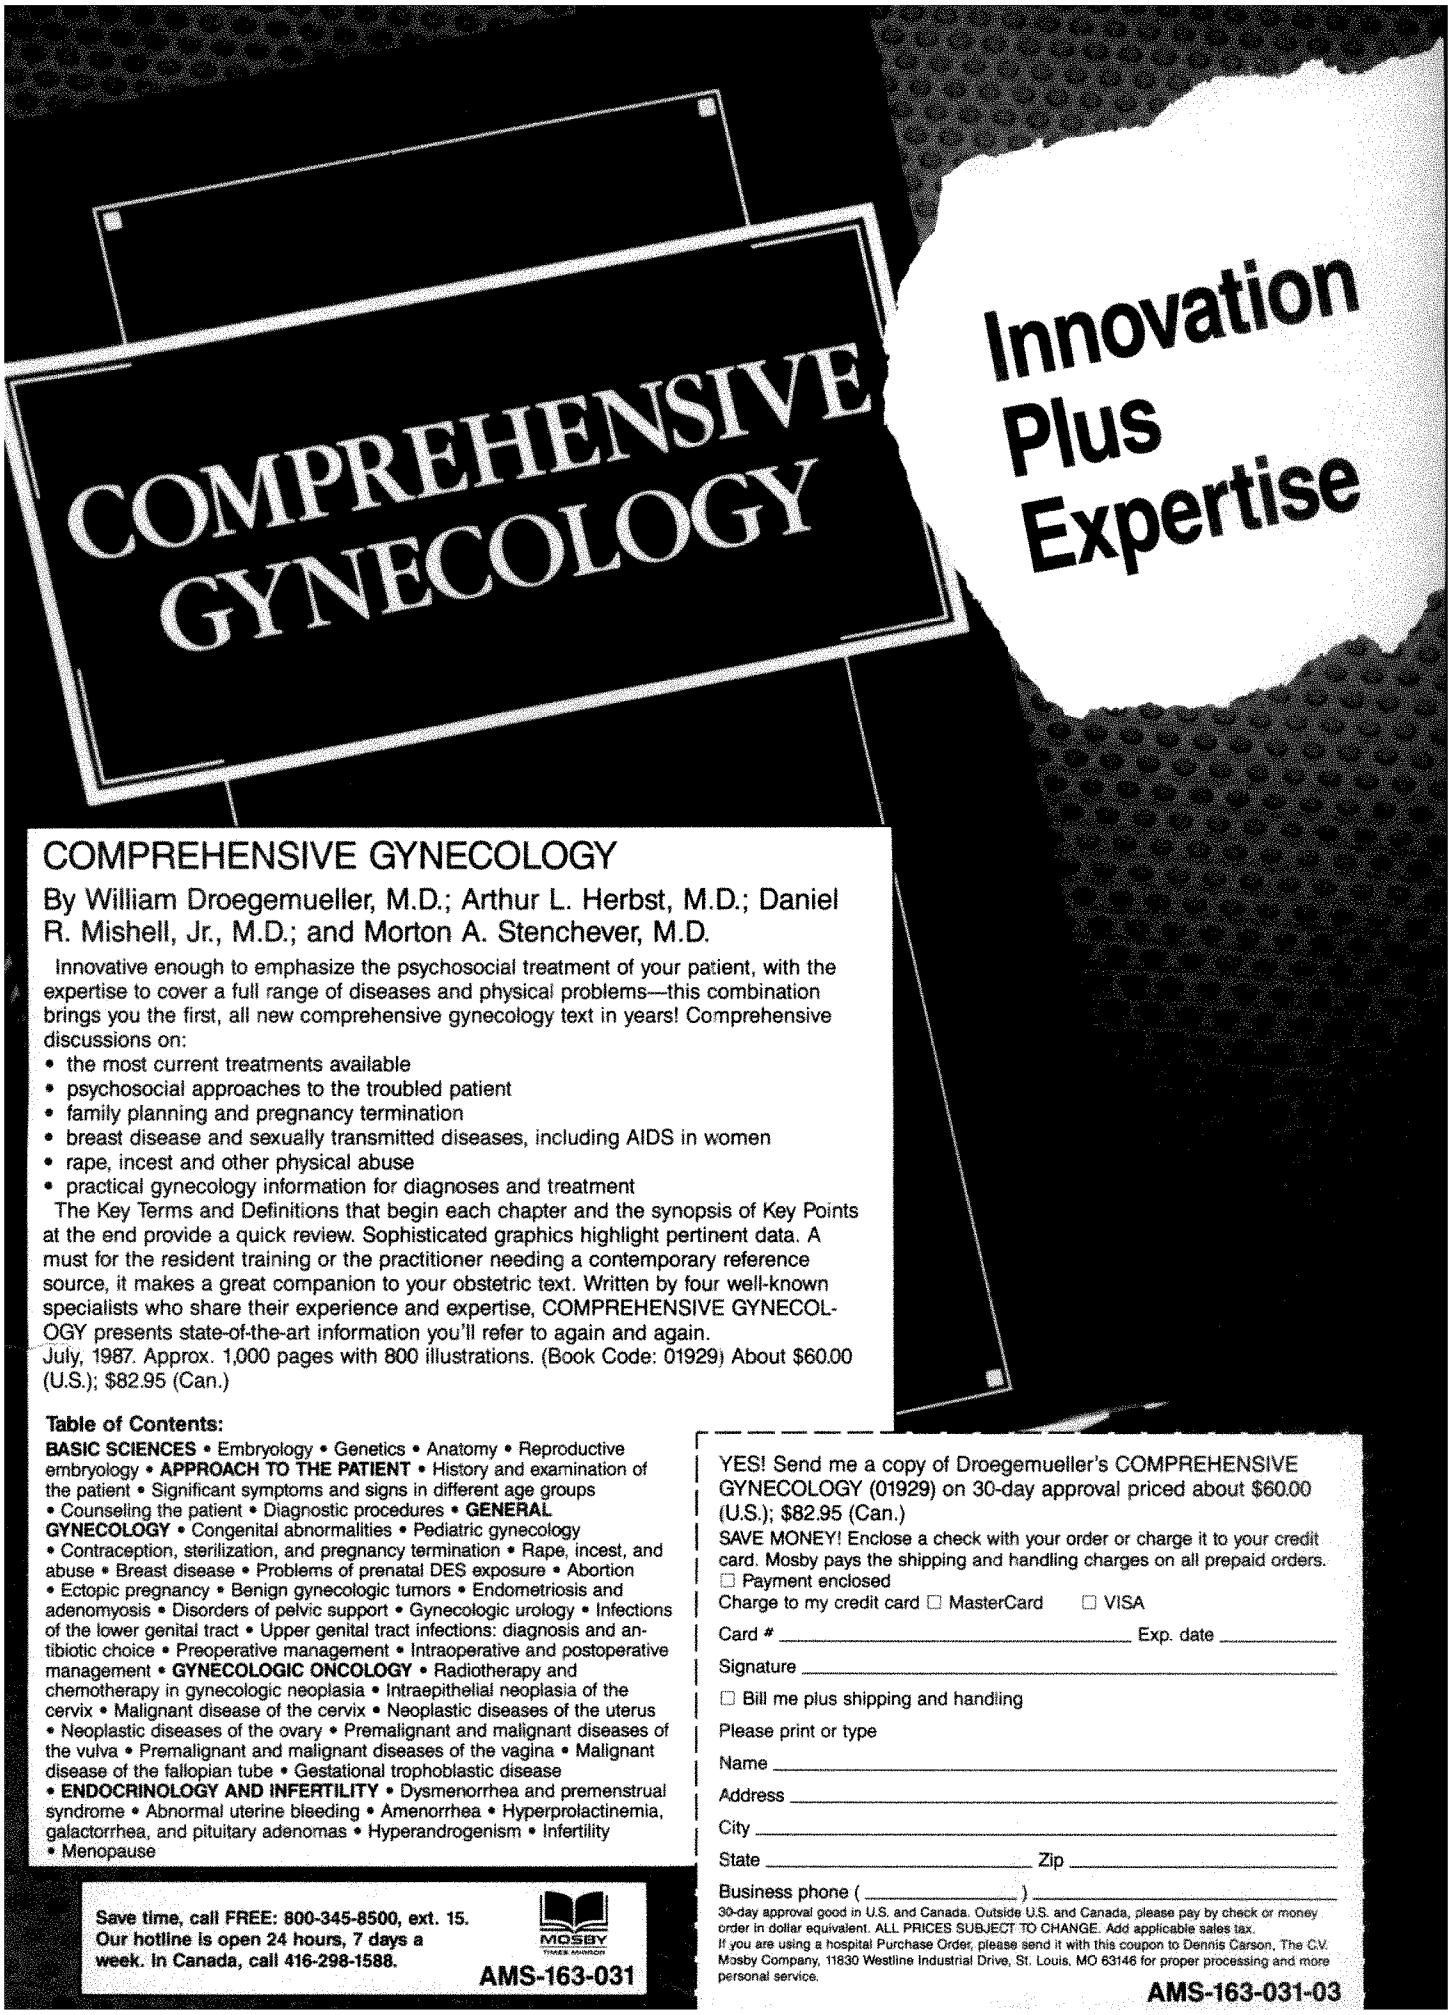
Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Information for the Patient*—See text of Patient Package Insert. *Pregnancy Category X*—See Contraindications and Boxed Warning. *Nursing Mothers*—Administer to nursing mothers only when clearly necessary.

The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes.



For Prescribing Information, please see physician package insert.

COMPREHENSIVE GYNECOLOGY

By William Droegemueller, M.D.; Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; and Morton A. Stenchever, M.D.

Innovative enough to emphasize the psychosocial treatment of your patient, with the expertise to cover a full range of diseases and physical problems—this combination brings you the first, all new comprehensive gynecology text in years! Comprehensive discussions on:

- the most current treatments available
- psychosocial approaches to the troubled patient
- family planning and pregnancy termination
- breast disease and sexually transmitted diseases, including AIDS in women
- rape, incest and other physical abuse
- practical gynecology information for diagnoses and treatment

The Key Terms and Definitions that begin each chapter and the synopsis of Key Points at the end provide a quick review. Sophisticated graphics highlight pertinent data. A must for the resident training or the practitioner needing a contemporary reference source, it makes a great companion to your obstetric text. Written by four well-known specialists who share their experience and expertise, COMPREHENSIVE GYNECOLOGY presents state-of-the-art information you'll refer to again and again.

July, 1987. Approx. 1,000 pages with 800 illustrations. (Book Code: 01929) About $60.00 (U.S.); $82.95 (Can.)

Table of Contents:

BASIC SCIENCES • Embryology • Genetics • Anatomy • Reproductive embryology • **APPROACH TO THE PATIENT** • History and examination of the patient • Significant symptoms and signs in different age groups • Counseling the patient • Diagnostic procedures • **GENERAL GYNECOLOGY** • Congenital abnormalities • Pediatric gynecology • Contraception, sterilization, and pregnancy termination • Rape, incest, and abuse • Breast disease • Problems of prenatal DES exposure • Abortion • Ectopic pregnancy • Benign gynecologic tumors • Endometriosis and adenomyosis • Disorders of pelvic support • Gynecologic urology • Infections of the lower genital tract • Upper genital tract infections: diagnosis and antibiotic choice • Preoperative management • Intraoperative and postoperative management • **GYNECOLOGIC ONCOLOGY** • Radiotherapy and chemotherapy in gynecologic neoplasia • Intraepithelial neoplasia of the cervix • Malignant disease of the cervix • Neoplastic diseases of the uterus • Neoplastic diseases of the ovary • Premalignant and malignant diseases of the vulva • Premalignant and malignant diseases of the vagina • Malignant disease of the fallopian tube • Gestational trophoblastic disease • **ENDOCRINOLOGY AND INFERTILITY** • Dysmenorrhea and premenstrual syndrome • Abnormal uterine bleeding • Amenorrhea • Hyperprolactinemia, galactorrhea, and pituitary adenomas • Hyperandrogenism • Infertility • Menopause

gainst the *B. fragilis* group?

94%

Mefoxin

active against 94% of isolates

the facts *still* favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group § and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group §, *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group §.

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia, a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (> 100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffe reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ® reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk. Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

OBSTETRICIAN GYNECOLOGIST-IN-CHIEF

The Mary Imogene Bassett Hospital, a 189-bed, rural referral center, and major teaching affiliate of Columbia University, is seeking candidates for this key appointment. The chief is responsible for overall clinical and teaching programs in Obstetrics and Gynecology. The Service is providing approximately 500 deliveries and about 4300 obstetrical clinic visits yearly. Volume in Gynecology is about 290 admissions and 7800 clinic visits. The department has four attending physicians, rotating transitional residents, a certified nurse midwife, a physician's assistant, plus substantial nursing and office staffing.

Cooperstown, on scenic Lake Otsego about 60 miles west of Albany, enjoys unusual recreational opportunities, a strong school system, and an array of cultural and artistic activities. The village is known for its air of history, museums and resort facilities.

The medical staff is organized as a salaried group practice with full fringe benefits including malpractice coverage, generous free time, conference leave, and immediate annuity participation.

Please send curriculum vitae and correspondence to:

Harlan D. Alpern, M.D.
Search Committee Chairman
The Mary Imogene Bassett Hospital
Cooperstown, New York 13326

THE MARY IMOGENE
BASSETT HOSPITAL

Michael Reese Health Plan
A LARGE HOSPITAL-BASED HMO

has openings for the following full-time position:

Obstetrician Gynecologist

THE MICHAEL REESE HEALTH PLAN, a well-established and rapidly-expanding, federally-qualified HMO seeks Board Certified/Eligible Obstetrician/Gynecologists.

THIS POSITION entails both outpatient and hospital practice as well as medical students and house staff teaching.

REMUNERATION is high and competitive with academic and fee-for-service practice markets. Fringe benefits are generous.

INTERESTED APPLICANTS should send Curriculum Vitae in confidence to:
Dr. Stephen Contro, Medical Director, MICHAEL REESE HEALTH PLAN, 2545 Martin Luther King Drive, Chicago 60616

an equal opportunity employer m/f/h

Proliferation of group B streptococci in human amniotic fluid in vitro

Iffath A. Abbasi, Lieutenant Commander, MC, USNR,
Val G. Hemming, Colonel, MC, USAF, Gary S. Eglinton, Colonel, MC, USAF, and
Timothy R. B. Johnson, Major, MC, USAF
Bethesda, Maryland

The group B *Streptococcus* is one of the most virulent organisms causing perinatal infection. Human amniotic fluid from the second and third trimesters was pooled and analyzed for electrolytes, protein, albumin, zinc, inorganic phosphorus, ferritin, lysozyme, and immunoglobulins. We inoculated replicates of specimens with known virulent strains of group B streptococci (893, 891, and 878) and *Escherichia coli* (C_5) with Todd-Hewitt broth and normal saline solution used as controls. Group B streptococci strains 893 and 891 proliferated rapidly at rates similar to their rates in Todd-Hewitt Broth. Strain 878 grew at a rate slower than that of strains 893 and 891. The amniotic fluid specimens were similar with respect to factors reported as inhibitory to bacterial proliferation. Second- and third-trimester amniotic fluid supports the growth of group B streptococci as well as a culture medium optimized for bacterial growth. Strain-specific variance in group B streptococci growth rates in amniotic fluid may have clinical significance for those at risk for group B streptococci infection. (AM J OBSTET GYNECOL 1987;156:95-9.)

Key words: Group B streptococci, bacterial growth, amniotic fluid

Bacterial invasion and growth in amniotic fluid play an important role in infectious perinatal morbidity and mortality. Cattaneo[1] was the first to report the presence of antibacterial activity in amniotic fluid. Since then several investigators have identified a number of factors that have been reported to confer antibacterial properties to amniotic fluid. However, the presence of these factors does not conclusively explain the antibacterial activity.[2,3] Clinically, group B *Streptococcus* appears to be one of the most virulent organisms involved in perinatal infections. We analyzed human amniotic fluid for the various factors previously reported to alter its antibacterial activity and then plotted in vitro growth curves, during 24 hours, of known virulent strains of serotype III group B streptococci (strains 878, 891, and 893) in the amniotic fluid.

Material and methods

Amniotic fluid specimens were obtained, under aseptic conditions, by amniocenteses, performed either during the second trimester for fetal chromosomal analysis or during the third trimester for fetal lung maturation studies. All patients were free of infection and had received no medications other than prenatal vitamins or iron supplements. Blood- or meconium-stained fluid was excluded as was fluid yielding positive bacterial cultures. The specimens were centrifuged at 2000 rpm for 10 minutes at 10° C. Each specimen was filtered through a 0.45 μm filter to remove particulate matter. The fluid was then stored at −80° C until analysis.[4] All second-trimester amniotic fluid specimens were grouped into a single pool as were all third-trimester

specimens. Amniotic fluid from each pool was cultured to ensure sterility and analyzed for the factors previously reported to inhibit the bacterial growth in amniotic fluid. Measurements included the analysis of electrolytes, total proteins, albumin, zinc, inorganic phosphorus, transferrin, lysozyme activity, and immunoglobulin levels. Zinc levels were measured after wet digestion with nitric-sulfuric acid followed by measurement by atomic absorption at 214 nm in air-acetylene flame with the use of a Perkin-Elmer atomic absorption instrument (Model 603, Beckman Instruments, Inc., Fullerton, California). Extensive precautions were required to avoid contamination of the samples by atmospheric dust, a common source of traces of zinc. All glassware was washed with acid before use. Transferrin levels were quantitated by means of the single radial immunodiffusion technique previously described by Larsen et al.[5] Lysozyme activity was measured with a commercial assay kit (Sigma Chemical Company, St. Louis, Missouri).

To plot the bacterial growth curves, paired 2 ml aliquots of amniotic fluid were inoculated in duplicate at zero time with approximately 1×10^4 CFU/ml of known virulent strains of serotype III group B streptococci (878, 891, and 893) and with strain C_5 *Escherichia coli*. Inocula were prepared by growing the group B streptococci to log phase (6 hours) in Todd-Hewitt broth, then adjusting the concentration to 1×10^9, cfu/ml, washing in sterile nonbacteriostatic normal saline solution, and adjusting to a concentration of approximately 1×10^4 cfu/ml. Twenty microliters of the saline solution group B streptococci or *E. coli* suspensions was inoculated into each amniotic fluid specimen. The specimens were mixed well; aliquots were removed for quantitative cultures and incubation was begun at 37° C in room air. Aliquots of 2 ml of Todd-Hewitt broth and of normal saline solution were used as positive and negative controls, respectively.

Duplicate 10 μl aliquots were removed at 2, 4, 6, and 24 hours from each specimen. After careful mixing, quantitative cultures were performed by successive tenfold dilutions of each sample followed by inoculation of a measured volume of each dilution onto blood agar plates. After overnight incubation at 37° C, colony counts were performed. The resulting growth curves were analyzed.

Results

The electrolytes, glucose, calcium, and total protein levels were within the normal ranges and were similar

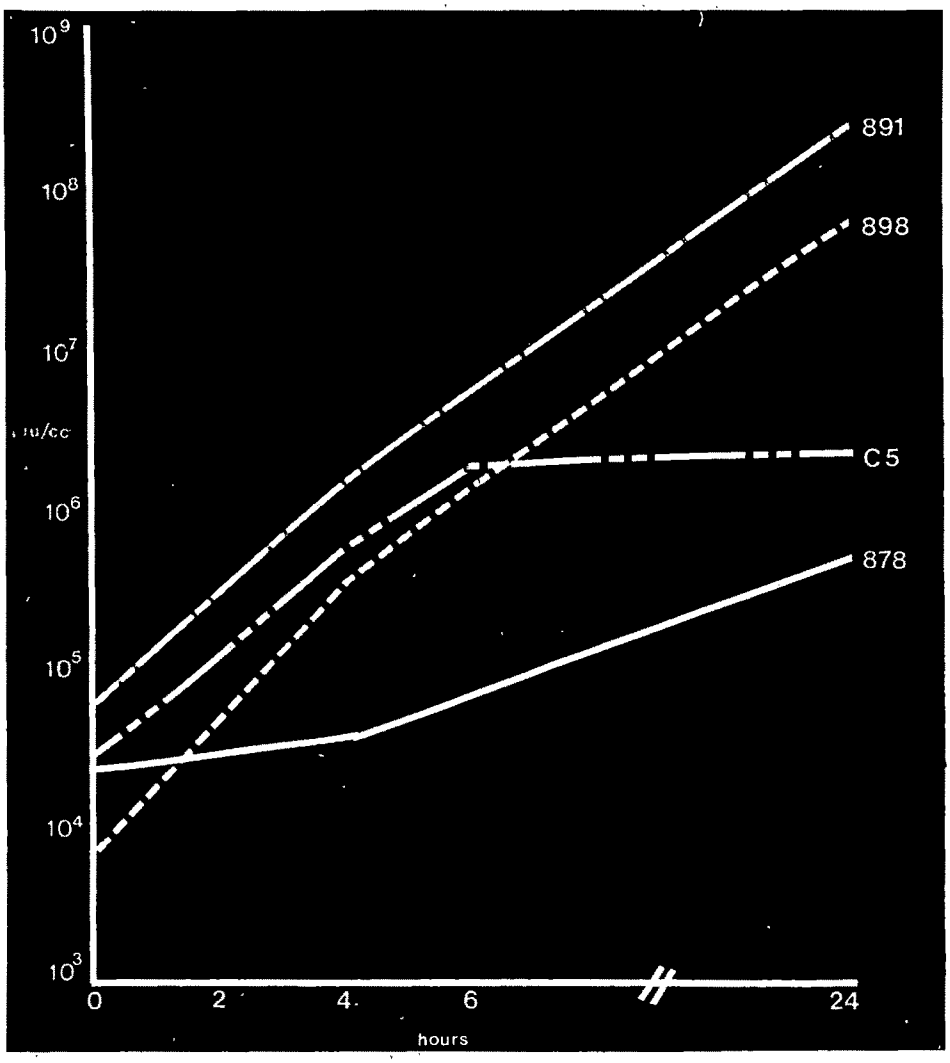

Fig. 1. Serotype III group B streptococci (strains 893, 891, and 878) and *E. coli* (strain C_5) growth curves during 24 hours in second-trimester human amniotic fluid.

in the two pools (Table I). The transferrin levels were similar to those previously reported for human amniotic fluid. Inorganic phosphorus values were also similar in the two pools, as were the zinc levels. The calculated ratio of inorganic phosphorus to zinc was >200. The lysozyme concentrations in the two pools were within the ranges previously reported for amniotic fluid. Immunoglobulin levels were not found in the amniotic fluid in amounts detectable by the radial immunodiffusion method.

Tables II and III show the results of the assays of the two pools during 24 hours for serotype III group B streptococci strains 878, 891, and 893, *E. coli* strain C_5 in amniotic fluid, Todd-Hewitt broth, and normal saline solution, and group B streptococci strain 893 in Todd-Hewitt broth and normal saline solution. All three strains of serotype III group B streptococci proliferated in amniotic fluid. The growth of 893 in amniotic fluid equaled or exceeded its growth in the positive control medium, Todd-Hewitt broth, whereas there was a log 1 decrease in colony-forming units per milliliter in the negative control, normal saline solution, which is not a nutrient medium.

Figs. 1 and 2 show a log-linear display of the growth curves for group B streptococci strains 893, 891, and 878 and *E. coli* C_5 in second- and third-trimester amniotic fluid. Strain 893 proliferated in both the second- and third-trimester pools at rates that exceeded its growth in Todd-Hewitt broth. Even though all three strains did proliferate in human amniotic fluid, they did so at different rates. Strain 878 did not match the apparently more aggressive strains 893 and 891. Fig. 2 shows the same growth curves in third-trimester amniotic fluid, thereby permitting a direct comparison of the three strains and once again demonstrating their different rates of growth in human amniotic fluid.

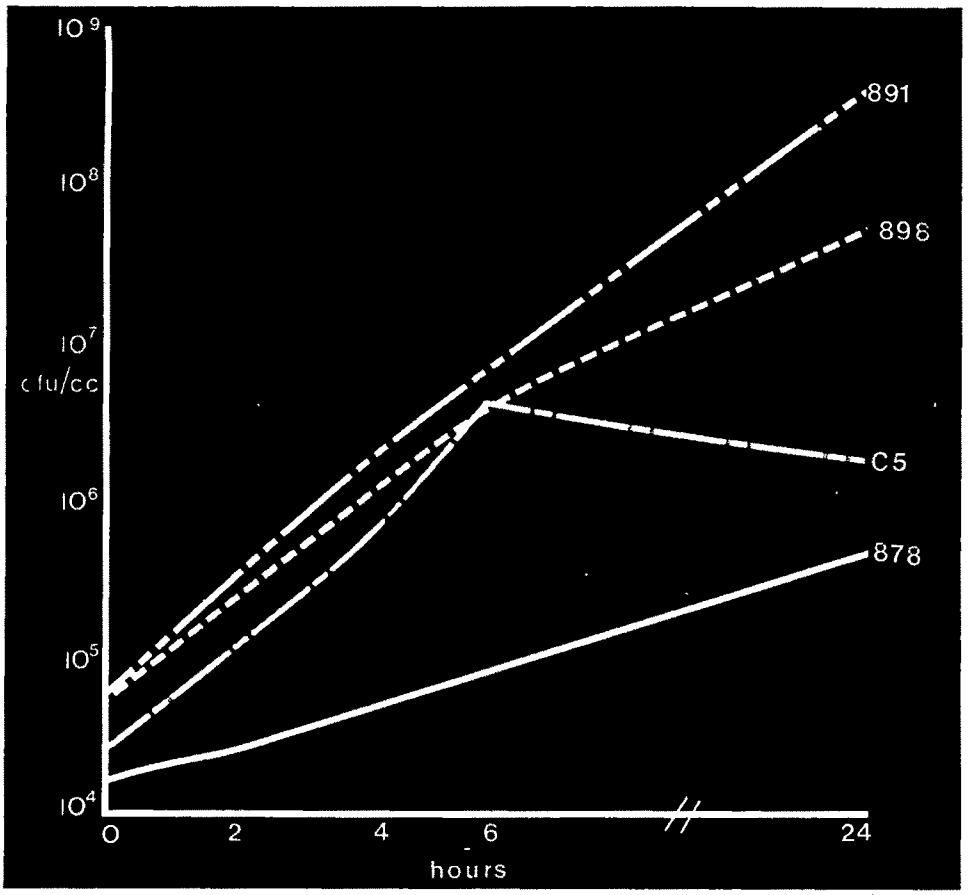

Fig. 2. Serotype III group B streptococci (strain 893, 891, and 878) and *E. coli* (strain C_5) growth curves during 24 hours in third-trimester human amniotic fluid.

Comment

Group B streptococci play an important role in bacterial infections of the mother and fetus. These organisms gain access to the amniotic fluid through ruptured or, more rarely, intact membranes and thereby present the fetus with a formidable bacterial challenge. While a substantial literature explores the various factors in amniotic fluid that impede bacterial growth, little is known about the influence of these factors on the prevention of the growth of group B streptococci. It has been reported that transferrin is capable of suppressing bacterial growth. Larsen et al.[5] have reported levels of transferrin concentrations in amniotic fluid with increasing gestational ages. These values correlate well with the levels found in our assays. Whether the zinc peptide complex inhibits proliferation of group B streptococci in amniotic fluid in vivo is uncertain. Schlievert et al.[6] isolated a zinc peptide complex that inhibits the proliferation of certain organisms in amniotic fluid. They demonstrated that ratios of inorganic phosphorus to zinc in amniotic fluid were predictive of the antibacterial activity of the fluid. A ratio of <100 was bactericidal, a ratio of 100 to 200 was bacteriostatic, and a ratio exceeding 200 was noninhibitory. However, these authors did not test this ratio against the growth of group B streptococci in amniotic fluid. In the present study, the group B streptococcal organisms proliferated to levels exceeding 1×10^7 CFU/ml in the presence of a ratio of inorganic phosphorus to zinc >200.

It has long been recognized that lysozymes play a role in host resistance. As early as 1949, Cattaneo[1] reported that amniotic fluid contained lysozyme-like activity. Since then, other authors have reported its presence and have quantified its levels in amniotic fluid.[7, 8] The levels obtained by our assays compared favorably with those reported by these authors. Since immunoglobulins represent an important host defense mechanism in the body, their levels have been quantified and reported for both normal and infected amniotic fluid. While immunoglobulin levels were not detected by our assay methods, lower levels cannot be excluded by this study because the lower limit of detection of the assay was 20 mg/100 ml.

Hemming et al.[4] reported the strikingly rapid proliferation of group B streptococci as compared with that

of *E. coli* in human amniotic fluid. In the present study, all three strains of group B streptococci proliferated rapidly during 24 hours, as did *E. coli* C_5. Our growth curves are similar to those reported by these and other authors.[9] However, there was an interstrain variation in the growth curves of group B streptococci. Even though serotype strain 878 of III group B streptococci did proliferate rapidly, as previously noted, it did so at a rate significantly lower than that of strains 893 and 891. Although growth curves of group B streptococci during 24 hours are not visually linear during the full 24-hour period, most curves are statistically linear when tested by linear regression analysis, which permits their comparison and allows demonstration of the differences in growth curves of the different strains in amniotic fluid. This variation may possibly be due to the accumulation, during 24 hours, of the metabolic end products of the bacteria that leads to a fall in pH and hence a deleterious effect on the growth and proliferation of these organisms, or it may be due to the consumption of nutrients that are essential to the growth of these organisms in the amniotic fluid.

Our preliminary data document strain-specific variation in growth rates of group B streptococci in human amniotic fluid in vitro. The identification of this variance may have important clinical significance for women and neonates at risk for group B streptococcal infection.

Urinary diagnostic indices in preeclampsia-associated oliguria: Correlation with invasive hemodynamic monitoring

Wesley Lee, M.D., Bernard Gonik, M.D., and David B. Cotton, M.D.
Houston, Texas

Seven oliguric women with preeclampsia were identified among patients admitted for obstetric care at Jefferson Davis or Hermann Hospitals in Houston, Texas. Urinary diagnostic indices (including urine-to-plasma ratios of creatinine, urea nitrogen, and osmolality) were generally consistent with a prerenal etiology for the observed oliguria. Conversely, invasive hemodynamic monitoring revealed a volume replete state in five of seven preeclamptic women studied. All patients were observed to have markedly elevated urinary sodium concentrations. The transient oliguria observed in these patients spontanously resolved without diuretic or hyperosmolar agents. We conclude that oliguria is a poor index of volume status in preeclamptic women. Urinary diagnostic indices may also be misleading if used to guide fluid management in these patients. Finally, the clinical significance and therapeutic alternatives relating to preeclampsia-associated oliguria are discussed. (Am J Obstet Gynecol 1987;156:100-3.)

Key words: Oliguria, preeclampsia, pulmonary artery catheter

Urinary output is commonly regarded as a clinical index of volume status and renal function. In the presence of oliguria, urinary diagnostic indices have been used in nonpregnant patients to differentiate between prerenal and renal etiologies.[1] Oliguria is also a recognized peripartum complication of pregnancy-induced hypertension (PIH). However, a paucity of information regarding PIH-associated oliguria is presently available. Additionally, the validity of urinary diagnostic indices under these special circumstances has never been tested. An interinstitutional review recently identified seven preeclamptic women who developed oliguria and were followed by pulmonary artery catheterization. The present study examines PIH-associated oliguria with a indirect estimation of volume status, that is, the pulmonary capillary wedge pressure. Urinary diagnostic indices were simultaneously obtained to determine the clinical usefulness of this information relative to volume status as estimated by the hemodynamic monitoring.

Material and methods

The patient population was selected from preeclamptic women admitted to either Jefferson Davis Hospital or Hermann Hospital in Houston, Texas, during the period from February 1983 to December 1985. The diagnosis of preeclampsia included the criteria of newly onset gestational hypertension (>140/90 mm Hg) and proteinuria in the absence of preexisting renal disease. All patients received intravenous magnesium sulfate for seizure prophylaxis. A pulmonary artery catheter was percutaneously inserted under aseptic conditions for the determination of each patient's hemodynamic profile. Continuous monitoring of systemic blood pressure was provided by radial artery cannulation. Urine output was measured continuously with an indwelling Foley catheter. For the purposes of this study, oliguria was defined as urine output of <30 ml/hr for at least 2 consecutive hours. When oliguria was identified, blood and urine specimens were obtained for measurement of sodium, creatinine, urea nitrogen, and osmolality. Pulmonary capillary wedge pressure measurements were obtained during the oliguric phase. The pulmonary capillary wedge pressure was obtained with patients in the supine position supported by a wedge under the right hip. Intravenous fluid management was guided by hemodynamic parameters. No diuretics were employed during the study period. The blood and urine laboratory values were used to calculate urine-to-plasma ratios of sodium (U/P Na), creatinine (U/P Cr), urea nitrogen, and osmolality. Free excretion of sodium was calculated by the formula (U/P Na ÷ U/P Cr) × 100. The renal failure index was also calculated by dividing urinary sodium concentration (mEq/L) by (U/P Cr). The interpretation of urinary diagnostic indices was based on the criteria proposed by Miller et al.[1] (Table I). Data are reported as mean ± SD.

Results

Demographic data from the seven study patients are tabulated in Table II. All but one patient presented before term with a mean gestational age of 34 ± 3 weeks. The mean arterial pressure for the group was 125 ± 16 mm Hg. Study subjects were primigravid women with the exception of patient No. 4 (gravida 2, para 1-0-0-1).

Table III summarizes pulmonary capillary wedge pressures and urinary diagnostic indices from each of these patients. The mean urine output was 23 ± 6 ml/hr. The mean pulmonary capillary wedge pressure was 8.7 ± 4.0 mm Hg. In only two patients (Nos. 3 and 7) was there evidence of intravascular hypovolemia as estimated by pulmonary capillary wedge pressure. The remainder suggested a volume replete state with normal to slightly elevated pulmonary capillary wedge pressure values.

Table IV allows classification of the urinary diagnostic indices by prerenal and intrarenal causes on the basis of criteria previously described (Table I). For most patients the urinary diagnostic indices could not be uniformly attributable to either prerenal or intrarenal factors. In this regard all patients demonstrated an elevated urine sodium consistent with a intrinsic renal defect. Conversely, most of the remaining indices supported a prerenal picture. An exception was found in patient No. 4 in whom the indices all were consistent with intrinsic renal disease.

In five of seven patients a volume replete state was suggested by normal to slightly elevated pulmonary capillary wedge pressure. Within this normovolemic group, one patient showed urinary diagnostic indices suggesting intrinsic renal failure, one revealed a mixed pattern, and the remaining three demonstrated a prerenal picture. Of note, the only patient (No. 6) with diagnostic indices clearly consistent with a prerenal picture had one of the highest pulmonary capillary wedge pressure in this study.

Comment

This study examines PIH-related oliguria and demonstrates a poor correlation between this clinical parameter and low pulmonary capillary wedge pressure. In this series of seven oliguric patients, only two subjects were considered hypovolemic by invasive hemodynamic monitoring. Urinary diagnostic indices also did not appear to be a useful indicator of volume status in these patients. The majority of indices predicted prerenal dehydration in five of seven preeclamptic women despite pulmonary capillary wedge pressures consistent with euvolemia.

Since oliguria associated with PIH does not appear to be solely related to volume depletion it is probable that other etiologic factors are contributory. For example, Pritchard et al.[2] have suggested that impaired renal function commonly seen in eclamptic women is related to severe regional vasospasm. Our results demonstrating normal pulmonary capillary wedge pressures in oliguric women with PIH are consistent with this hypothesis.

The clinical significance of transient oliguria associated with PIH is controversial. Recently Hankins et al.[3] documented the relationship between elevated pulmonary capillary wedge pressures and delayed spontaneous postpartum diuresis in eclamptic women. They hypothesized that this phenomenon was secondary to the mobilization of extravascular fluid before diuresis. Such observations may account for the occurrence of postpartum cerebral and pulmonary edema in patients with PIH. Under these circumstances oliguria could potentially play an important role in the pathogenesis of these preeclampsia-related complications.

Traditional therapy of PIH-associated oliguria has included the use of diuretics, intravenous fluid challenges, and/or observation. Pritchard et al.[2] have admonished against the use of diuretics or hyperosmolar agents in antepartum women with PIH. They hypothesized that placental blood flow may be compromised by decreasing intravascular volume. Such a further reduction in regional blood flow might adversely affect the fetus, since preeclampsia alone is often associated with uteroplacental insufficiency.

The administration of intravenous fluids in the absence of accurate volume assessment may also be haz-

§Oliguria from intrinsic renal damage.

ardous. Our findings suggest that if urine output or urinary diagnostic indices were solely used to guide peripartum fluid management, the majority of these tests would indicate hypovolemia in preeclamptic women. On this basis these patients might inappropriately receive excessive intravenous fluids, placing them at higher risk for pulmonary or cerebral edema.

Invasive hemodynamic monitoring provides valuable information regarding the volume status of preeclamptic women with oliguria. If the pulmonary capillary wedge pressure is normal, the clinician may elect to observe the patient under the assumption that transient renal vasospastic factors are responsible for oliguria. In the presence of prolonged oliguria, the clinician may feel compelled to treat the patient despite a normal range of pulmonary capillary wedge pressures. If regional vasospasm is a major determinant of the PIH-associated oliguria, it might be beneficial to use an agent that could selectively improve renal perfusion. Gerstner and Grunberger[4] studied nine eclamptic patients with oliguria who were treated with intravenous dopamine (3 μg/kg/min) after minimal improvement in urine output despite furosemide or osmodiuretic administration. Although the clinical usefulness of this drug has not been verified, these investigators reported an improvement in urine output following dopamine infusion.

Dopamine is a metabolic precursor of norepinephrine and epinephrine which is produced by the kidney and may act intrarenally as a natriuretic hormone.[5] In low doses, dopamine's β-adrenergic action predominates, leading to increased renal plasma flow and glomerular filtration rate by a specific vasodilatory effect on the kidney vasculature. Huss et al.[6] have demonstrated that the urinary excretion of dopamine is significantly higher in preeclamptic women when compared to normal pregnancies. This observation may be related to the high urine sodium levels uniformly seen in our patients.

The clinician should be cautioned that low urine output alone does not necessarily reflect a hypovolemic state in preeclamptic women. Additionally, the several urinary diagnostic indices cited in this report do not appear to reliably reflect intravascular volume depletion. Finally, from a clinical perspective, the primary treatment of severe PIH and its complications is delivery.

We would like to thank Karen Dorman, R.N., and Marilyn Seibel, R.N., for their meticulous assistance.

Adjunctive magnesium sulfate infusion does not alter metabolic changes associated with ritodrine tocolysis

James E. Ferguson II, M.D., R. Harold Holbrook, Jr., M.D., David K. Stevenson, M.D., Paul A. Hensleigh, M.D., Ph.D., and Daniel Kredentser, M.D.

Stanford and San Jose, California

Magnesium sulfate, an agent whose cellular actions might cause metabolic disturbances, has been used concomitantly with ritodrine hydrochloride for preterm labor tocolysis. Although the profound metabolic effects of β-adrenergic agents have been well described, the possibility that adjunctive magnesium might cause further or unexpected alterations in maternal metabolic parameters has not been fully evaluated. To investigate this question, we prospectively randomized patients, in a blinded fashion, to receive ritodrine plus placebo or ritodrine plus adjunctive magnesium sulfate for preterm labor tocolysis. Serial measurements of potassium, glucose, blood urea nitrogen, and hematocrit were obtained and compared between tocolytic treatment groups. The metabolic changes found were similar in each group and appear to result predominantly from β-adrenergic stimulation with no apparent perturbations caused by the direct cellular actions of magnesium sulfate. From the metabolic standpoint, it appears that the clinician may use adjunctive magnesium sulfate without fear of accentuating or obscuring the expected β-adrenergic–induced alterations in the above-mentioned maternal metabolic parameters. (AM J OBSTET GYNECOL 1987;156:103-7.)

Key words: Magnesium sulfate, ritodrine, preterm labor, tocolysis, metabolic effects

β-Adrenergic agents are widely used in obstetrics in an effort to inhibit preterm labor and thereby prevent premature delivery and the possible accompanying adverse fetal and neonatal sequelae. The maternal metabolic effects associated with the intravenous use of these agents have been documented and include hyperglycemia,[1] hypokalemia,[1] hyperinsulinemia,[1] hyperlactacidemia,[1] and decreased bicarbonate,[2] hematocrit,[2] and colloid osmotic pressure values.[1]

Recently, we[3] and others[4, 5] have investigated the adjunctive use of magnesium sulfate with ritodrine for preterm labor tocolysis. Although some have advocated this combined approach, the possibility of dual-agent tocolysis causing further or unexpected alterations in maternal metabolic parameters has not been fully investigated. In an effort to address this clinically important issue, we prospectively evaluated potassium, glucose, blood urea nitrogen, and hematocrit in a group of patients who were randomly chosen to receive either ritodrine with adjunctive magnesium sulfate or ritodrine plus placebo.

Material and methods

A prospective, randomized, blinded clinical trial was designed in which patients in preterm labor were divided into two treatment groups (Table I). Obstetric management of these patients has been previously described,[3] but salient aspects will be reviewed. Informed

consent, as approved by the Institution's Research and Human Subjects Review Committee, was obtained from each patient. Patients in preterm labor (regular uterine contractions with a documented change in cervical effacement or dilatation before 36 weeks' gestational age) were randomly assigned to receive either ritodrine with adjunctive magnesium sulfate (N = 28) or ritodrine plus placebo (N = 22) for tocolysis. In addition, the randomization specified the intravenous solution for each patient: 5% dextrose in water, 5% dextrose in half normal saline solution, or lactated Ringer's solution. The infusion containing adjunctive magnesium sulfate consisted of 40 gm of magnesium sulfate in 500 ml of the preselected intravenous fluid, whereas the placebo infusion for "ritodrine plus placebo" patients consisted of 500 ml of the preselected intravenous fluid devoid of magnesium sulfate. Both the magnesium sulfate and placebo solutions were labeled as "study solution" and were visually indistinguishable. Intravenous solutions were prepared by a nurse, not otherwise involved in the patient's care, who selected a sealed envelope from a previously randomized file. Thus the physician and nurse attending the patient were unaware of the contents of the "study solution." The ritodrine solution contained 150 mg of ritodrine hydrochloride in 500 ml of intravenous fluid. The ritodrine solution and "study solution" were infused by separate, continuous infusion devices. The single preselected electrolyte solution was used in each patient and served as the vehicle for the ritodrine solution and the "study solution" as well as for baseline fluid maintenance given to achieve a total infusion of 100 ml/hr.

During treatment, standard practice was followed for the administration of the ritodrine solution.[3] Simultaneously with the initiation of the ritodrine infusion, the study solution infusion was begun at a predetermined rate: 105 ml in the first hour, 60 ml during the second hour, and 30 ml/hr thereafter. Thus, if the study solution contained magnesium sulfate, 8.4 gm of magnesium sulfate was delivered in the first hour, 4.8 gm in the second hour, and 2.4 gm/hr thereafter. Only the ritodrine rate was altered in response to uterine activity; the rate of infusion of the "study solution" (whose contents were unknown to the managing physician and nurse) was identical for all patients.

Laboratory evaluation before tocolysis and at 6, 12, and 24 hours after the initiation of therapy included measurements of hematocrit and serum concentrations of potassium, glucose, and blood urea nitrogen. Maternal and fetal monitoring, use of amniocentesis, and steroid administration as well as the timing or use of oral β-adrenergic agents followed our standard practice and have been previously described.[3, 6]

Hematocrit was measured with a Coulter-S (Coulter Electronics, Hialeah, Florida). Serum potassium and blood urea nitrogen concentrations were determined by an Astra-8 Autoanalyzer (Beckman Instruments, Brea, California). Serum glucose was measured by the glucose oxidase automated method by the Astra-8 Autoanalyzer.

Statistical analysis was performed with the use of χ^2 analysis with Yates' correction for continuity, Student's t test (for paired and unpaired samples as appropriate) or one-way analysis of variance.

Results

Fifty patients were enrolled in the study; 28 were randomized to ritodrine and adjunctive magnesium sulfate and 22 patients received ritodrine plus placebo. Ten patients were withdrawn from the study for the following indications: mature lecithin/sphingomyelin ratio (n = 7), serious tocolytic side effect before 6 hours requiring discontinuation of tocolytic agent (n = 1), chorioamnionitis (n = 1), and gestational diabetes (n = 1). Final analysis of metabolic factors therefore included 40 patients who had completed at least 6 hours of intravenous tocolytic therapy: 23 received ritodrine and adjunctive magnesium sulfate and 17 received ritodrine plus placebo.

Because patients were randomly selected to receive one of three intravenous solutions as well as one of the tocolytic regimens, a comparison was made with the use of one-way analysis of variance of all metabolic values between the different solution groups. Six patients received 5% dextrose in water, 18 patients received 5% dextrose in half normal saline solution, and 16 patients received lactated Ringer's solution. No differences were detected between the three solution groups for any of the values (hematocrit, blood urea nitrogen, glucose,

Differences between tocolytic study groups at each time interval were not significant (unpaired *t* test, $p > 0.05$).

Table II. Comparison of maternal baseline values with interval values for hematocrit and blood urea nitrogen, glucose, and potassium concentrations

*Value**	*Baseline (pretreatment)*	*6 hr*	*12 hr*	*24 hr*
Hematocrit (%)	34.7 ± 3.9 (6/18/16‡)	32.7 ± 3.8† (6/18/16)	31.7 ± 3.6† (5/17/12)	29.6 ± 3.7† (5/8/10)
Blood urea nitrogen (mg/100 ml)	7.3 ± 2.1 (6/18/16)	6.6 ± 2.0† (6/18/16)	6.2 ± 1.9† (5/16/11)	5.9 ± 1.2† (5/8/10)
Glucose (mg/100 ml)	87 ± 27 (6/18/16)	175 ± 45† (6/18/16)	159 ± 34† (5/17/12)	133 ± 24† (5/8/10)
Potassium (mEq/L)	3.9 ± 0.4 (6/18/16)	3.1 ± 0.4† (6/18/16)	3.5 ± 0.4† (5/17/12)	3.4 ± 0.4† (5/8/10)

*Values are mean ± SD.
†$p < 0.01$, compared with baseline value (paired *t* test).
‡Number of patients receiving electrolyte solutions A/B/C.

and potassium) at any of the time periods (baseline, 6 hours, 12 hours, and 24 hours). The values for patients in the three solution groups were therefore combined to allow comparison of the two drug regimens.

Comparisons of the four metabolic variables between the two tocolytic treatment groups at each of the four time periods are shown in Fig. 1. No significant differences were noted between the two treatment groups for any of the four variables at any of the time periods ($p > 0.05$, unpaired *t* test).

Since no differences were noted between treatment groups, the groups were then combined to assess changes over a period of time in the metabolic values studied. So that each patient served as her own control, comparisons made included only those patients for whom data were available at both initiation of therapy and the time period being tested. Values for all patients at 6, 12, and 24 hours after initiation of therapy are compared with baseline (pretreatment) values in Table II. Hematocrit, blood urea nitrogen, and potassium values fell and glucose rose significantly at 6 hours after initiation of treatment. Values for all four variables remained significantly different from baseline levels at 12 and 24 hours as well ($p < 0.01$, paired *t* test). To assure that the differences observed over a period of time were not the result of changes in the distribution of patients among the three solution groups, the proportion of patients receiving each solution was compared for 6, 12, and 24 hours; no differences were noted (see Table II).

Comment

The profound metabolic effects of β-adrenergic tocolytic agents are well known. To date, however, the possibility that adjunctive magnesium sulfate might accentuate or obscure metabolic changes has not been

fully considered. Our aim in this report was to determine, by using a prospective, blinded, randomized study, if dual-agent tocolysis consisting of ritodrine and magnesium sulfate might cause further or unexpected changes in maternal metabolic values.

Magnesium sulfate is an effective tocolytic agent with complex cellular mechanisms of action. The major tocolytic action of magnesium sulfate is likely mediated by the extracellular magnesium ion concentration that affects uptake, binding, and distribution of cellular calcium in smooth muscle. It appears that extracellular magnesium ions decrease total exchangeable and membrane-bound calcium at smooth muscle membranes by competing with or displacing calcium ions at cell membrane binding sites.[7] Magnesium sulfate may also have an effect on the cyclic nucleotide system within the cells. Magnesium activates adenylate cyclase, an enzyme involved in the synthesis of cyclic adenosine monophosphate (cAMP).[7] Increases in the levels of cAMP in smooth muscle promote relaxation because (1) cAMP-mediated phosphorylation inhibits the activity of myosin light-chain kinase (the predominant enzyme in the regulation of smooth muscle contractility) and (2) cAMP promotes the accumulation of calcium by the sarcoplasmic reticulum and thus depresses intracellular free calcium concentrations to levels at which the myosin light-chain kinase is not active.[8] The effect of magnesium on cAMP is of particular interest because there are data to suggest that increased cAMP concentrations act to promote vasodilation.[9] If so, then with fluid administration during magnesium tocolysis, one would expect to encounter an expanded intravascular volume. This could be clinically recognized by the finding of a hemodilutional fall in hematocrit.

β-Adrenergic agents also affect fluid balance. The antidiuretic hormone effect of β-adrenergic agents leads to the inability to excrete a sodium load and, coupled with fluid administration, may cause volume overload.[1] Although Hankins et al.,[10] using the pregnant baboon model, could demonstrate no difference in serial hematocrits or colloid oncotic pressures measured in animals receiving intravenous ritodrine, they did note significant increases in sodium and water retention when compared with that in controls. Decreases in hematocrit and colloid osmotic pressure regularly accompany the clinical use of β-adrenergic tocolytic agents in humans.[1,2] Although the potential for an exaggerated effect on hematocrit exists when these agents are used concomitantly, we were unable to demonstrate such an effect (Fig. 1). In our study, the expected decrease in serially monitored hematocrits occurred in both groups. Similarly, blood urea nitrogen values did not differ between groups and decreased in both groups during therapy. Although Philipsen et al.[2] could not demonstrate a significant change in blood urea nitrogen levels during ritodrine treatment, our results are consistent with an expected hemodilutional fall in blood urea nitrogen.

Hyperglycemia was noted in both our patient groups. β-Adrenergic agonists are believed to induce hyperglycemia by increasing the rate of glycogenolysis and/or gluconeogenesis.[1,11] The findings of decreased plasma alanine levels with accompanying increases in glucose levels in patients receiving β-adrenergic therapy support the etiologic role of gluconeogenesis.[12] Magnesium, too, is a controlling and coordinating factor in carbohydrate metabolism. While the administration of physiologic levels of magnesium does not modify blood glucose, high doses of magnesium result in hyperglycemia.[13] This effect is believed to be due to the endogenous release of epinephrine and inhibition of insulin secretion. Additionally, magnesium may affect the affinity and number of insulin receptors. Hatjis et al.[4] recently reported on a group of retrospectively evaluated preterm labor patients in whom magnesium sulfate was added because of ritodrine failure. It is interesting to note in their study that hypokalemia (25 of 30) and hyperglycemia (28 of 30) occurred significantly more often if one combines the two subgroups who received ritodrine and magnesium sulfate and compares them with the patients who received ritodrine alone (19 of 35 and 21 of 35, respectively, $p = 0.0095$ and $p = 0.00156$, Fisher's exact test). Differing results are not unexpected when one considers the dissimilar study designs.

Magnesium concentration is integrally involved in determining the intracellular potassium, calcium, and sodium concentrations.[14] Although the direct effect of magnesium excess on the cell membrane could induce elevated intracellular potassium and resultant hypokalemia, in practice the compensatory mechanisms relating to magnesium and potassium cellular metabolism are so effective that one rarely encounters clinically detectable hypokalemia.[14,15] Richards et al.[11] reported insignificant changes in potassium levels in a small group of women receiving magnesium sulfate for preterm labor tocolysis. Our patients demonstrated similar degrees of hypokalemia in both the adjunctive magnesium and ritodrine plus placebo groups. Cano et al.[16] recently clarified the limited role of β-adrenergic–induced hyperglycemia and resultant hyperinsulinemia in the genesis of hypokalemia. They suggest that hypokalemia is likely a result of stimulation of the β_2-receptors by ritodrine leading to activation of the ionized sodium–ionized potassium adenosine triphosphatase and resultant translocation of potassium across the cellular membrane.[16]

In summary, the adjunctive use of magnesium sulfate, when administered as described herein, does not cause further or unexpected alterations in the maternal

potassium glucose, blood urea nitrogen, or hematocrit values. The metabolic changes found were similar in each group and are predominantly the result of the β-adrenergic stimulation with no apparent perturbations caused by the direct cellular actions of magnesium sulfate. From the metabolic standpoint, it appears that the clinician may use adjunctive magnesium sulfate without fear of accentuating or obscuring the expected β-adrenergic–induced alterations in the above-described maternal metabolic parameters.

We wish to thank Ruby Mei-Lun Wong, Ph.D., for her able assistance with the statistical evaluation of our data.

Radioimmunoscintigraphic detection of occult gestational choriocarcinoma

Richard L. Wahl, M.D., M. B. Khazaeli, Ph.D., Albert F. LoBuglio, M.D., R. A. Patillo, M.D., Michael J. Tuscan, C.N.M.T., and William H. Beierwaltes, M.D.

Ann Arbor, Michigan, Birmingham, Alabama, and Milwaukee, Wisconsin

Localized recurrent gestational choriocarcinoma, evidenced by a rising level of the β-subunit of human chorionic gonadotropin, can be difficult to localize for surgical resection. We describe a patient with a rising level of the β-subunit of human chorionic gonadotropin after extensive therapy for choriocarcinoma in which gamma scanning of the distribution of an intravenously administered iodine 131–labeled monoclonal antibody preparation (5F9.3) allowed localization of a focus of recurrent choriocarcinoma in the lung. Other imaging methods showed this only as a focus of stable scarring. The antibody scan guided surgical resection of this tumor focus, which on gamma counting had a tenfold excess of antibody activity compared with that of the normal lung. This approach may be useful in detecting occult foci of gestational choriocarcinoma for surgical resection in patients with rising levels of the β-subunit of human chorionic gonadotropin and is under further evaluation. (AM J OBSTET GYNECOL 1987;156:108-11.)

Key words: Gestational choriocarcinoma, radioimmunoscintigraphy, monoclonal antibody

Choriocarcinoma, a human chorionic gonadotropin (hCG)–secreting neoplasm of trophoblastic origin (in women), has become increasingly effectively controlled by chemotherapy.[1] While aggressive chemotherapy can frequently cause remissions, even of pulmonary lesions, surgical resection of such lesions may still have a role if such a patient with choriocarcinoma has a persistently elevated level of hCG, has no other metastases, and has contraindications to additional chemotherapy.[1, 2] Detection of such foci of active tumor in the lungs can be difficult, particularly if a patient has pulmonary scarring.[2] While radiolabeled polyclonal anti-hCG antibodies have been used to detect foci of choriocarcinoma in animals and patients, they have not yet been able to detect occult pulmonary disease.[2-5] The use of monoclonal antibodies for radioimmunoscintigraphy may offer advantages over polyclonal reagents.[6-8] We recently applied radioimmunoscintigraphy with an iodine 131–labeled monoclonal antibody originally raised against embryonal testicular cancers (5F9.3), which was unreactive with hCG but reactive with the majority of choriocarcinoma cell lines tested to date, to successfully detect a clinically occult pulmonary focus of choriocarcinoma.[9-11]

Case report

A 29-year-old woman was referred with a 4-year history of choriocarcinoma. The tumor was first diagnosed in 1981, when she became anemic 2 months after a spontaneous abortion. The anemia was due to uterine rupture caused by choriocarcinoma. Although pelvic disease was largely resected at operation, pulmonary metastases were then noted to be present. Chemotherapy and pelvic irradiation produced a remission by August 1981, but a recurrence was diagnosed 3 months later. Since that time she has had two abdominal operations: (1) removal of the ovaries and (2) resection of a pelvic recurrence. She has also had two right thoracotomies for pulmonary nodule resection and has had a total of 45 cycles of chemotherapy, including bleomycin, methotrexate, actinomycin D, VP-16, and Adriamycin. Pulmonary scarring secondary to the operations and also as a result of the bleomycin therapy has been noted on multiple chest radiographs and computerized tomographic scans. With the chemotherapy, the serum level of β-subunit of hCG (β-hCG) had nearly normalized 4 months before presentation to the University of Michigan Medical Center and chemotherapy was discontinued.

Approximately 2 months before presentation, she was noted to have a rising β-hCG level, which increased further during the next 2 months to 2980 IU when she was admitted to the University of Michigan Medical Center. Three abdominal and chest computerized tomographic scans obtained during the months before admission, including a scan immediately preceding ad-

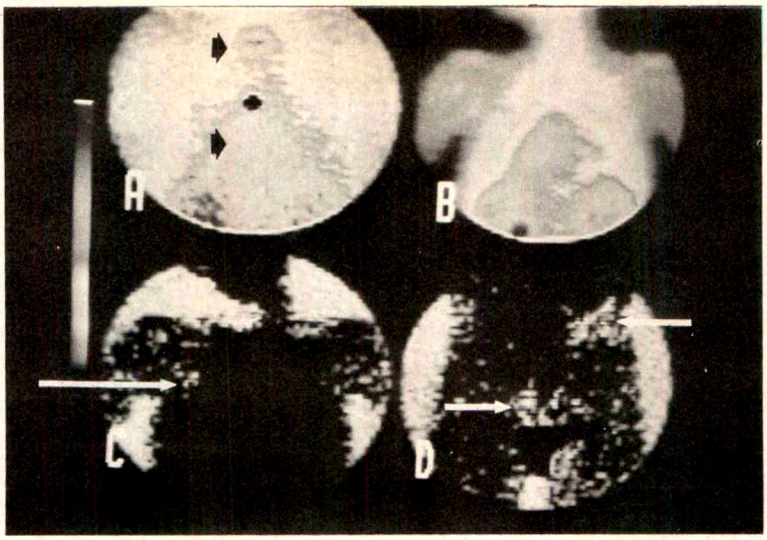

Fig. 1. *A*, ^{131}I-labeled gamma antibody images at 120 hours of posterior chest demonstrating increased activity in thyroid *(upper arrow)*, heart *(lower arrow)*, liver, spleen, and left side of the chest. Black *cross* represents a computer artifact. *B*, Tc99m human serum albumin image obtained 120 hours after antibody infusion and ½ hour after Tc99m human serum albumin injection. This image was obtained simultaneously with *A*, with the use of dual-energy acquisition. *C*, Selected ^{131}I-labeled image with Tc99m human serum albumin background subtracted. Note focal increased activity in left side of the chest *(arrow)*. *D*, ^{131}I-labeled abdominal image (after background subtraction of Tc99m human serum albumin image) showing increased activity in the lower abdomen *(lower arrow)* and in the stomach *(upper arrow)*. (This may be due to free iodine in the stomach and gut as the result of antibody deiodination with subsequent trapping in fluid-filled bowel, caused by partial small bowel obstruction, although the patient had a history of tumor recurring near the bladder.)

mission, were interpreted as "status post hysterectomy with no obvious abdominal disease and stable scarring of the upper lung fields." She was thus admitted to undergo a search for a site of occult disease.

After informed consent was obtained, the patient received 1.25 mCi of ^{131}I-labeled murine monoclonal antibody 5F9.3 intravenously. This represented approximately 1 mg of mouse antibody, labeled by the iodogen technique. The patient was maintained on a regimen of SSKI, three drops/day, throughout the study. She tolerated the injection without adverse effects. Gamma scans with a gamma camera having a large field of view and interfaced to a high-energy collimator were obtained daily until 6 days after injection. These scans, evaluating the entire body of the patient, included 100,000 counts or 20 minutes of acquisition. All data were stored in a dedicated nuclear medicine computer for subsequent analysis. Blood pool subtraction images were generated at 48 and 120 hours after antibody injection, by subtracting the simultaneously acquired Tc99m human serum albumin blood pool image obtained 30 minutes after injection of 1 mCi of Tc99m human serum albumin[5] from the ^{131}I-labeled antibody image. These background subtracted images were then displayed cinematically on a computer monitor with variable levels of background subtraction for final interpretation.[12]

Images examined as above showed a persistent focus of increased activity in the left side of the chest (on posterior images). This was seen best with background subtraction at 48 and 120 hours (Fig. 1, *A* to *C*) and without background subtraction at 6 days after injection. Moderate activity was also noted in the lower abdomen (Fig. 1, *D*), although plain film radiographs obtained at the time of imaging showed a partial small bowel obstruction pattern, with dilated small bowel loops (this problem has been present intermittently since pelvic irradiation).

Review of the chest radiographs in the left upper lung field region, at the site of the increased uptake seen on antibody scan, suggested to some observers the presence of a small nodule in a region of pulmonary scarring; however, the abnormality was extremely subtle and overlay the scapula (Fig. 2). Review of several computerized tomographic scans showed density in the left upper chest corresponding to the area of increased uptake seen on antibody scans. This area had been read longitudinally as representing stable scarring (Fig. 3).

A fine needle aspiration biopsy of the left upper chest scarring was performed 2 weeks after imaging, and the cytologic test results were positive for choriocarcinoma. The slide of this aspirate also underwent gamma counting, and resulting counts were compared with those from a similar-sized aspirate of adjacent normal lung cells from this patient. A tenfold ^{131}I count excess was found in the slide with the aspirate that was positive for tumor when compared with the normal lung aspirate. The patient subsequently underwent a thora-

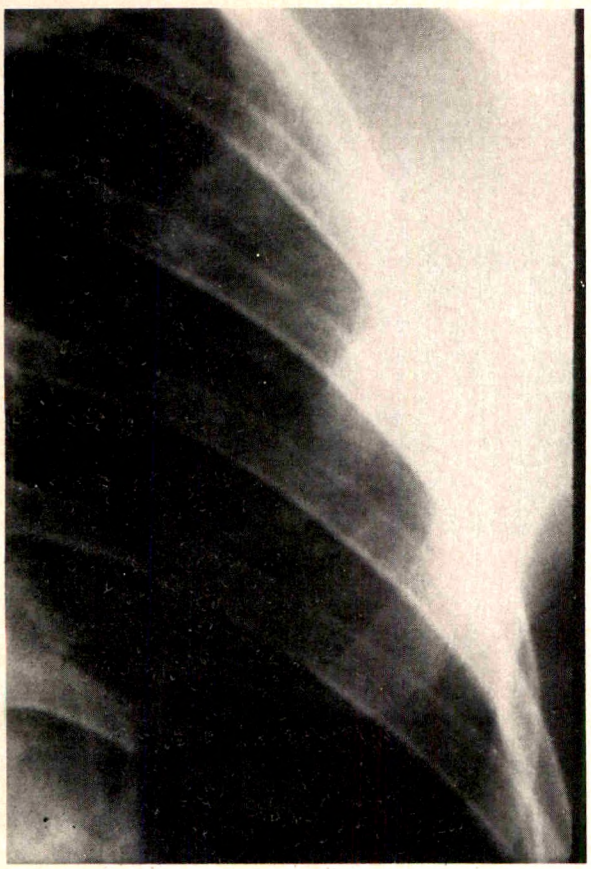

Fig. 2. Close-up view of left upper side of the chest appearing essentially normal in region of increased uptake on antibody scan. On the original film, however, some observers felt a small nodular density might overlie the scapula.

cotomy with resection of tumor. The β-hCG level remained elevated, and she has had two exploratory laparotomies to relieve small bowel obstruction. No abdominal tumor was found at either of these operations. The patient is currently being treated with additional chemotherapy as the β-hCG level remains elevated.

Comment

The ability of radiolabeled antibodies to hCG to localize to choriocarcinoma has been known for some time.[3] More recently, radiolabeled monoclonal and polyclonal antibodies to other tumors have been shown, in certain cases, to be capable of detecting small foci of disease that were undetectable as disease foci by other methodologies. For example, with the use of monoclonal and polyclonal antibodies, occult foci of colon cancer have been detected when computerized tomographic scans were normal.[13, 14] While detection of an occult abdominal focus of choriocarcinoma was reported in 1980 with the use of polyclonal antibodies,[3] this was at a time when computerized tomographic scanning was capable of less spatial and temporal resolution than current devices offer. Detection of "occult" foci of choriocarcinoma has been reported as successful mainly in men, including a series where computerized tomographic scanning was not conducted in all cases.[5] Labeled polyclonal anti-hCG antibodies have been shown to localize to viable choriocarcinoma in women as well, but in all cases other than that reported by Hatch et al.,[4] when there was positive antibody uptake, a definite x-ray or computerized tomographic abnormality highly suggestive of tumor was present.[2, 5]

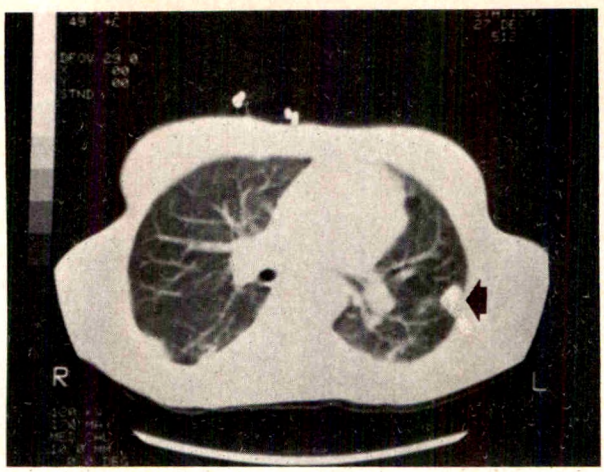

Fig. 3. Computerized tomographic scan of chest obtained 2 weeks before antibody scan demonstrating bilateral upper lobe scarring. Density in left side of the chest *(arrow)* had previously been interpreted as "stable scarring." On needle biopsy and resection this represented a focus of choriocarcinoma and corresponded exactly to the uptake seen on the antibody scan (Fig. 1, *C*).

In the patient described here, radioimmunoscintigraphy was capable of strongly suggesting that a detectable pulmonary abnormality, previously felt to represent scarring, was, in fact, a clinically occult focus of choriocarcinoma. This antibody uptake in the lesion, with biopsy verification, is gratifying and the tenfold excess accumulation over that in the normal lung suggests that it is due to antibody specificity for tumor. Studies in an animal model of choriocarcinoma have shown tumor uptake to be largely due to specific antibody binding.[10] Unfortunately, optimal images could be obtained only after blood pool subtraction, which emphasizes the relatively low tumor/background ratios achieved by many intact monoclonal antibodies.[15] While antibody fragments have helped this somewhat, these low ratios after intravenous antibody delivery represent a problem that must be overcome before more widespread use of this technique as a diagnostic or therapeutic modality can be reasonably considered.[15] Better labeling methods than iodine may also be useful.[16] This point is of particular potential relevance in this case, as increased activity was seen in the lower abdomen when imaging was done in this patient. This imaging oc-

curred at a time of partial small bowel obstruction and it is possible that the increased abdominal uptake was due to deiodination of antibody with accumulation into the bowel. Despite these issues, this considerably encouraging preliminary result, in a case that was difficult to diagnose, adds support to the possibility that radiolabeled monoclonal antibodies will have a role in the diagnosis of malignancies and, in particular, female choriocarcinomas. Studies in additional patients will be essential to define the sensitivity and specificity of this approach.

Thanks are extended to James Botti and Diane Lahti for imaging of patients. Thanks are also due to Steven Kronberg, Linda Laino, Gayle Jackson, Neil Petry, and Jeff Burke for technical assistance and advice in antibody preparation.

Corticosteroid levels in human fetal blood at midgestation and at term

A. López Bernal, E.O.G., D.Phil., and Ian Z. MacKenzie, M.D.
Oxford, England

Cortisol and cortisone were estimated in samples of fetal blood obtained by fetoscopy at 13 to 24 weeks' gestation and in cord blood obtained at elective cesarean section at 38 weeks' gestation. Levels of cortisone exceeded those of cortisol at all gestational ages studied. At midgestation, cortisol levels tended to fall with advancing gestation and had a weak negative correlation with fetal weight. The levels of both steroids were similar in male and female fetuses and increased significantly from midgestation to term. (Am J Obstet Gynecol 1987;156:112-3.)

Key words: Cortisol, cortisone, fetal blood, fetoscopy

Despite the abundant literature on human fetal corticosteroid levels near term, information about corticosteroid levels in fetal blood at midgestation is limited. In a previous study[1] cortisol was measured in samples of cord blood obtained from fetuses delivered by hysterotomy at 15 to 20 weeks' gestation, but there is little information about steroid levels in second-trimester human fetuses before delivery. Pure fetal blood can be obtained at fetoscopy with minimal disturbance to the fetus,[2] and in this article we present data on cortisol and cortisone levels in samples obtained by this technique.

Material and methods

Heparinized cord blood was obtained at fetoscopy in women scheduled for elective abortion. Details of the procedure have been given previously.[2] All women gave informed consent and the study had local ethical approval. Only blood samples from singleton fetuses with no apparent abnormalities were included. Mixed cord blood samples were obtained at elective cesarean sections at term. Cesarean sections were performed because of previous cesarean sections or to deliver infants conceived by in vitro fertilization; all newborn infants were normal.

Plasma samples were separated and stored at −20° C. Cortisol and cortisone were measured by radioimmunoassay after chromatography on Sephadex LH-20.[3] Interassay and intra-assay coefficients of variation were <10% for cortisol and <16% for cortisone.

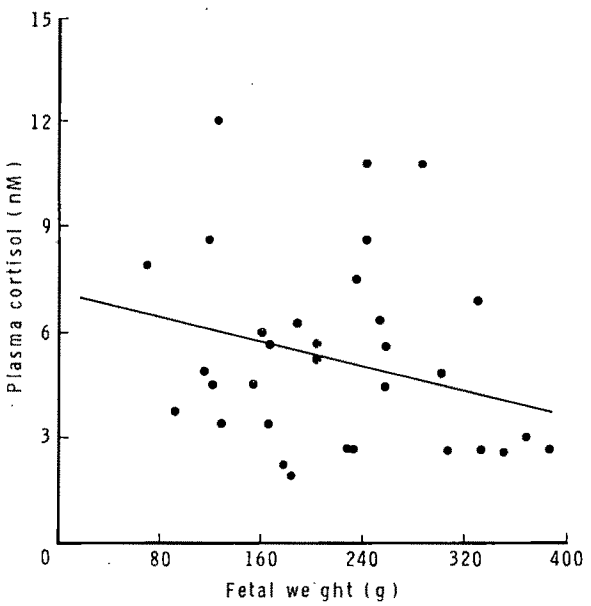

Fig. 1. Correlation between fetal weight (x) and cortisol levels (y) in fetal blood obtained by fetoscopy at 13 to 24 weeks' gestation. Best-fit straight line: $y = 7.01 - 0.01x$; $p > 0.05$.

The data were assessed by the Kruskal-Wallis, Mann-Whitney, and Spearman rank correlation tests.

Results

The data are summarized in Table I. Levels of cortisone exceeded those of cortisol at all gestational ages studied and the levels of both steroids were similar in male and female fetuses. Cortisol and cortisone levels at 38 weeks were significantly higher ($p < 0.001$) than the levels obtained at 13 to 24 weeks' gestation, but the cortisol/cortisone ratio remained similar. At midgestation cortisol levels tended to fall with advancing gestational age and so did the cortisol/cortisone ratio. Overall (Kruskal-Wallis test) these changes were not

statistically significant. However, in view of previous evidence[1] of a fall in fetal cortisol levels at 18 weeks' gestation, the data were reanalyzed with a comparison of samples obtained before and after 18 weeks, and the differences were significant at $p < 0.05$. Cortisone levels remained relatively stable throughout the midtrimester. The midgestational fall in cortisol levels was also apparent when the results were plotted as a function of fetal weight (Fig. 1) but failed to reach statistical significance (Spearman rank correlation coefficient = -0.26, $p > 0.05$).

Comment

This study provides detailed information on cortisol and cortisone levels in midtrimester fetal blood obtained at fetoscopy. The levels reported here are likely to represent those found in utero in the undisturbed fetus, without the possible stressing effect of delivery. Our data confirm that there is a fall in fetal cortisol levels at about 18 weeks' gestation,[1] but the significance of this fall is weakened by the high p value and by the poor negative correlation between fetal cortisol levels and fetal weight. This apparent fall in fetal cortisol levels has been attributed[1] to the change in the size of the adrenal gland relative to body weight that occurs at midgestation; however, at that stage the bulk of the fetal adrenal cortex composes the "fetal zone," which secretes mainly 3β-hydroxy-5-ene steroids, and cortisol output is relatively small.[4] It is not well established what factors regulate fetal cortisol levels at midgestation, but these levels probably depend on maternofetal exchange as well as fetal adrenal cortisol production. Cortisol levels in maternal blood[5] and in amniotic fluid[6] increase significantly with advancing gestation with no evidence of a fall in the midtrimester.

Comparison of the samples obtained by fetoscopy with those obtained at elective cesarean section at term confirms that there is a true rise in fetal cortisol levels between midgestation and term independent of the influence of labor,[1] and our data show that there is a parallel rise in fetal cortisone levels. In the absence of labor or other factors that might stimulate the fetal adrenal, the cortisol/cortisone ratio in fetal blood would largely be regulated by placental 11β-hydroxysteroid dehydrogenase, and it is of interest that the activity of this enzyme in vitro is similar in midgestation and at term.[7] In summary, our data demonstrate that there is an absolute rise in fetal cortisol and cortisone levels between midgestation and term but the cortisol/cortisone ratio remains stable.

The technical assistance of Mrs. Sue Phipps is gratefully acknowledged.

Anticardiolipin antibodies and complement in ninety-nine women with habitual abortion

A. Margareta Unander, M.D., Ph.D., Renée Norberg, M.D., Ph.D., Lennart Hahn, M.D., Ph.D., and Leopold Årfors, M.D.

Göteborg and Stockholm, Sweden

Immunologic investigations were performed on sera from 99 women with habitual abortion (three or more consecutive miscarriages). All were considered healthy and clinical investigations had not revealed any cause for the miscarriages. Sixty-eight were considered to have primary habitual abortion whereas 31 had secondary habitual abortion. Increased anticardiolipin antibody levels were found in 42 patients. None had a primary diagnosis of systemic lupus erythematosus, but at follow-up studies one of them fulfilled the diagnostic criteria of systemic lupus erythematosus. Ten sera, all from patients with primary habitual abortion, showed high anticardiolipin antibody values (≥10 units) concomitant with significantly lower levels of complement factor C4 than those found in sera with moderate or normal anticardiolipin antibody levels. There was no indication of genetic defects explaining the low C4 values, which could be explained at least in part by an activation of complement by the classical pathway. (Am J Obstet Gynecol 1987;156:114-9.)

Key words: Habitual abortion, anticardiolipin antibody, complement factors, antinuclear antibody

Recent studies have revealed a high incidence of repeated fetal loss in patients with systemic lupus erythematosus and concomitant antibodies against negatively charged phospholipids, primarily cardiolipin.[1-6] These antibodies frequently occur in systemic lupus erythematosus and their association with thromboembolic manifestations has been demonstrated.[7] However, high titers of anticardiolipin antibodies have occasionally been found in patients without systemic lupus erythematosus and also in these patients concomitant with thromboembolic episodes. Antibodies to cardiolipin are rarely demonstrated in healthy control subjects but can occasionally be demonstrated, for instance, in patients with acute infections. In these cases, however, the anticardiolipin antibodies seem to occur temporarily whereas in patients with systemic lupus erythematosus the production is constant and apparently rather independent of the disease activity.[8]

We have investigated the occurrence of anticardiolipin antibodies in sera from 99 consecutive female patients referred to us because of recurrent fetal loss. All were considered healthy and no obvious explanation for the abortions had been found. Increased anticardiolipin antibody levels were demonstrated in 42 women, 10 of whom had highly increased values. These 10 patients were followed up with repeated examinations including analyses of the reason for lowered values of complement factor C4 found in the sera.

Material and methods

Patient material. Ninety-nine women who had experienced at least three consecutive abortions, that is, fulfilled the diagnostic criteron of habitual abortion, were sent from all parts of Sweden for immunologic investigations. Clinical investigations including genetic karyotyping of the couples, determinations of antibodies against infectious agents, hysterosalpingography and/or hysteroscopy, and endocrine evaluations, had failed to reveal any cause for the abortions. The women were considered healthy. None of them suffered from any disease that could possibly explain the abortions, such as systemic lupus erythematosus or poorly controlled diabetes. Except for three of them, the women were not pregnant when investigated. Sixty-eight were considered to have primary habitual abortion; they had had three to 11 abortions and no deliveries (Table I). They had experienced a total of 278 pregnancies, six of which (2%) were extrauterine, whereas 221 (79%) had resulted in first-trimester miscarriages and 51 (18%) were second-trimester abortions. The 31 with secondary habitual abortion had been pregnant four to 10 times, and three to nine of the pregnancies had

resulted in abortions (see Table I). They had experienced 196 pregnancies, 41 of which (21%) had resulted in deliveries. However, only 30 of 196 pregnancies (15%) resulted in live infants, since 11 of the 41 infants suffered perinatal death due to immaturity, severe growth retardation, or a combination of both. Of the 196 pregnancies, 127 (65%) ended in first-trimester miscarriages whereas 28 (14%) resulted in second-trimester fetal losses. Eight women with secondary habitual abortion had had two deliveries, yet four of them had no living children since they had repeatedly experienced premature deliveries of growth-retarded infants who died during the perinatal period. Two of these eight women had their two infants with previous partners so they indeed had primary habitual abortion in their current relationship. Another woman with secondary habitual abortion had experienced three very premature deliveries of severely growth-retarded infants, only one of whom had survived.

Assay of anticardiolipin antibody. Antibodies against cardiolipin were determined essentially as described by Harris et al.[7] but with the use of an enzyme-linked immunosorbent assay technique and alkaline phosphatase–conjugated antihuman IgG and IgM antibodies, respectively. The results were given in units whereby one unit corresponded to the mean control value plus 1 SD of the mean. Values above or equal to three units were considered pathologic. The control material consisted of healthy blood donors and has been described earlier.[8]

Assay of complement components. Complement components Clq, C3, and C4 were quantified by rocket electrophoresis by means of standard routine techniques.[9] C2 was studied by crossed immunoelectrophoresis as described by Sjöholm and Sturfelt.[10] The presence of C4A and C4B, respectively, was demonstrated by crossed immunoelectrophoresis and by sodium dodecyl sulfate–polyacrylamide gel electrophoresis.[11]

Antinuclear antibodies. Antibodies against nuclear antigens were demonstrated by indirect immunofluorescence with the use of cryostat sections of rat tissue and smears of *Crithidia luciliae* for antibodies to double-stranded deoxyribonucleic acid.

Circulating immune complexes. The Clq and solid-phase conglutinin techniques performed as used by Lambert et al.[12] were used to demonstrate circulating immune complexes in serum.

Statistical calculations. The differences between mean values were analyzed with the use of Student's *t* test for paired comparisons. Significant differences ($p < 0.01$) are indicated in the tables.

Results

Increased anticardiolipin antibody levels were demonstrable in 42 of 99 women with habitual abortion (Table II). Cardiolipin antibodies exclusively of the IgM class were found in sera from seven patients. The IgM values were low (three to seven units). IgG antibodies against cardiolipin were demonstrated in sera from 35 patients, 10 of whom, all with primary habitual abortion, showed values ≥10 units (Table II).

There were no differences in the mean ages (Table I) or numbers of miscarriages (data not shown), respectively, between the various groups of women with different levels of anticardiolipin antibodies. The group of women with high levels of anticardiolipin antibodies (≥10) consisted only of those with primary habitual abortion (Table II). There were no differences

in the proportions of primary and secondary habitual abortion between the other groups of women with various levels of anticardiolipin antibodies (Table II).

The levels of complement components C3 and C4 were determined in the first serum specimen available from 32 of 35 patients with IgG anticardiolipin antibodies. As can be seen from Table III the mean value of C4 in sera with anticardiolipin antibody levels of ≥10 units was significantly lower than that in sera with values of anticardiolipin antibody between three and nine units ($p < 0.01$). The mean value of the latter group did not differ significantly from that of healthy control subjects. The mean values of C3 were normal and statistically the same in the two groups.

Antinuclear antibodies were demonstrated in sera from a total of nine patients, four of whom were anticardiolipin antibody negative, one had anticardiolipin antibodies of IgM class only, and the remaining four belonged to the group with IgG anticardiolipin antibody values ≥10 units (Table IV). The antinuclear antibody titers were low (1/10 to 1/25) in sera from all women except one in whom antibodies to double-stranded deoxyribonucleic acid also could be demonstrated. This patient fulfilled the diagnostic criteria of systemic lupus erythematosus although her clinical symptoms were mild and mainly characterized by arthralgia.

The 10 patients with the highest anticardiolipin antibody levels (≥10 units) were followed up with consecutive analyses for at least 12 months. The anticardiolipin antibody levels were rather unaffected by pregnancy and therapy during the observation period as exemplified in Figs. 1 and 2. The normal C3 levels and the low C4 values were also rather constant. During prednisolone treatment in pregnancy some patients displayed a tendency of the C4 values to increase toward normal levels, as illustrated in Fig. 2.

IgG antibodies to cardiolipin were found in subclasses 1 to 4, with certain individual variations of the relative distribution (Table IV).

The cause of the decreased C4 values was studied in sera from the seven patients with the highest anticardiolipin antibody values by analyzing the presence of the two C4 gene products C4A and C4B by crossed immunoelectrophoresis and sodium dodecyl sulfate–polyacrylamide gel electrophoresis. In all serum samples but one the presence of C4A as well as C4B could be demonstrated (Table IV). Thus there was no indication of an increased frequency of two silent C4 alleles within the same locus explaining the low C4 values.

Activation of the early components of the classical pathway was studied in plasma by quantitation of Clq and by measuring the amounts of cleaved C2 by crossed immunoelectrophoresis (Table IV). The Clq values were all within the normal ranges, whereas in all patients investigated cleaved C2, C2a, was demonstrated by crossed immunoelectrophoresis. C2a was not found in normal plasma. Accordingly, the decreased C4 levels could at least partly be explained by an activation of complement by the classical pathway.

Circulating immune complexes were demonstrated by either one or both techniques used in eight of the 10 sera investigated (Table IV).

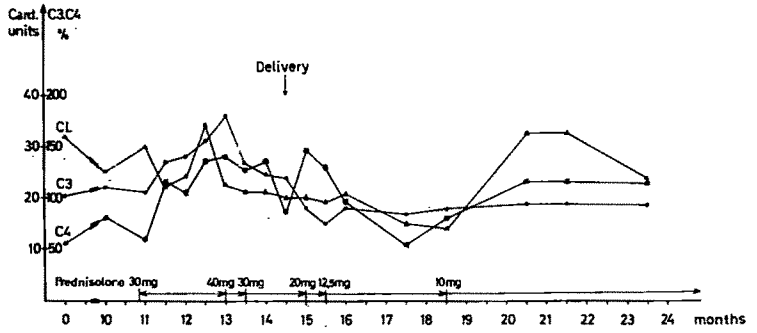

Fig. 2. The levels of anticardiolipin antibodies and complement factors C3 and C4 of Patient E. L., 35 years of age. She had experienced her sixth miscarriage in week 11, 2 months before the first blood sampling. The second blood sample was drawn 10 months later, in pregnancy week 14. Prednisolone treatment was initiated in pregnancy week 17. In week 33 she was delivered by cesarean section of a healthy female infant weighing 1680 gm.

Comment

Our patient material consisted of a consecutively referred nonselected population of habitually aborting women (who had suffered three or more abortions), among whom obvious causes for the repeated abortions had been ruled out by clinical investigations. None of them was considered to have systemic lupus erythematosus when referred to us. It was therefore surprising to find that as many as 42% of them had elevated anticardiolipin antibody values, in 10 cases to very high levels (≥10 units).

Antibodies to cardiolipin were demonstrated in sera from a total of 42 patients. Seven of them had only IgM antibodies and 35 had IgG antibodies. Most of the latter also had demonstrable IgM antibodies. The anticardiolipin activity of purified IgM and IgG fractions was not investigated separately. Thus we do not know to what extent the outcome of the enzyme-linked immunosorbent assay determinations was influenced by the presence of both IgM and IgG antibodies, which might be of different affinity and avidity. Therefore, we have chosen to report the values of IgG anticardiolipin antibody levels. Moreover, in most cases the antibody activity of IgM was lower than that of IgG. The IgG anticardiolipin antibodies were demonstrated within IgG subclasses 1 to 4 (Table IV) although with individual quantitative variations.

Anticardiolipin antibodies are only rarely demonstrated in healthy control subjects.[7,8] Increased levels have been found mainly in patients with systemic lupus erythematosus in whom disease-raised anticardiolipin levels have been associated with thromboembolic manifestations as well as with recurrent abortions. Two of the 99 women with habitual abortion had had deep venous thromboses. They were found in the groups of women with anticardiolipin antibody levels of three to four and ≥10 units, respectively. None of our patients had a primary diagnosis of systemic lupus erythematosus but during the follow-up studies one patient with anticardiolipin antibody levels of ≥10 fulfilled the diagnostic critera of systemic lupus erythematosus.

Moderately increased levels of anticardiolipin antibodies are occasionally found in patients with various infections.[8] In those patients, however, the production of antibodies to cardiolipin seems to be temporary, as investigation of serum samples drawn a year after the original study showed a return to normal levels in all cases but one, in which the patient had a chronic staphylococcal infection.[8] The cause of these elevated anticardiolipin levels is unknown but they may be a part of a polyclonal antibody activation related to the acute infection.

The present anticardiolipin antibody levels were low or moderately elevated in sera from most women with habitual abortion, but in 10 cases (10%), all in women with primary habitual abortion, markedly high values (≥10 units) were registered and seven of the women had anticardiolipin values between 20 and 40 units. According to our experience levels of ≥10 units are very rare in patients with acute infections and values of ≥20 units are only occasionally seen in randomly selected patients with systemic lupus erythematosus and, if so, symptoms compatible with those of thromboses are present.[8] Our patients were followed up with repeated analyses during 15 to 48 months. As seen in Figs. 1 and 2 the anticardiolipin antibody levels were rather constant and independent of pregnancy and steroid therapy during the study. The same observation has been made in patients with systemic lupus erythematosus in whom the anticardiolipin antibody values usually are unrelated to disease activity and therapy.[8]

There were no differences in the mean ages (Table I) or numbers of miscarriages, respectively, between the various groups of women with different levels of

anticardiolipin antibodies. The group of women with high anticardiolipin antibody levels (≥10) consisted only of those with primary habitual abortion (Table II). The proportions of primary to secondary habitual abortion were the same, respectively, in the other groups of women with various levels of anticardiolipin antibodies (Table II).

Typical of most sera with highly raised anticardiolipin values were levels of complement factor C4 that were below or at the lower normal range whereas most of the C3 levels were well within the normal ranges (Table III). With few exceptions the same observations have also been made in patients with thromboembolic manifestations and high anticardiolipin levels (Norberg R, et al., unpublished observations).

The cause of the C4 decrease is not entirely clear. The production of C4 is governed by two gene loci, C4A and C4B, on chromosome six. About 20% of patients with systemic lupus erythematosus have been reported to have two silent alleles within the same locus in comparison with <5% in healthy control subjects.[13] Since only one of the 10 patients with high levels of anticardiolipin antibody lacked one of the gene products there was no obvious evidence for an increased incidence of genetic defects explaining the low C4 levels in these 10 patients. On the other hand, the C2 cleavage demonstrated by crossed immunoelectrophoresis indicated an increased complement activation by the classical pathway. The C3 values were with some exceptions normal, but this does not, however, exclude that the turnover of C3 also was increased. To what extent reactions between anticardiolipin antibodies and corresponding antigens contributed to the complement activation has not been investigated. Most of these 10 sera contained circulating immune complexes but the structure of these complexes has not been studied.

It was, however, remarkable that the C4 values remained low during the observation period in most cases. The patients had no clinical symptoms and they considered themselves healthy. The same observation has also been made in other patients, who have been followed up for several years after an acute thromboembolic episode.[8] They had continuously high levels of cardiolipin antibodies and low C4 values, which remained so during a long observation period without any signs of new thromboses[8] (Norberg R, et al., unpublished data).

The persistingly very high anticardiolipin antibody levels and signs of complement activation via the classical pathway as well as the increased frequency of antinuclear antibodies in 10 of the women with primary habitual abortion indicate that these women compose a special group exhibiting immunologic reactions with features similar to those of systemic lupus erythematosus. This justifies that these patients will be carefully surveyed with regard to the development of clinical symptoms of systemic lupus erythematosus.

The women with low or moderately increased levels of anticardiolipin antibodies did not stand out clinically from those with normal levels. There is no apparent explanation of their elevated anticardiolipin antibody levels. The women were not pregnant at the time of investigation and the time since the last miscarriage varied. The influence of pregnancy and abortion on the anticardiolipin antibody levels cannot be ruled out, the more so as the incidence of increased values during normal pregnancy is not known.

Negatively charged phospholipids as cardiolipin are constituents of all cell membranes. Antibodies to cardiolipin have been attributed pathogenic importance by interacting with, for example, platelets and vascular endothelial cells. In this way mechanisms may be provoked that can lead to an increased tendency for platelet aggregation and other cellular events of importance for the coagulation process.[3, 6] There is, however, no definite support for the direct pathogenic role of antiphospholipid/anticardiolipin antibodies either in patients with systemic lupus erythematosus[8] or in the pres-

ent group of aborting women. Treatment with prednisolone and minute doses of acetylsalicylic acid has resulted in living infants[1, 4] (Fig. 2), but the anticardiolipin levels were remarkably uninfluenced by the medication (Fig. 2) whereas the values of activated partial thromboplastin time decreased.[1, 14]

Eight of these women with habitual abortion with elevated anticardiolipin antibody levels (two of them had ≥10 units) who had no demonstrable blocking antibody received leukocyte transfusions[15] and subsequently had successful pregnancies without any therapy aimed at diminishing the autoimmune aberration. Therefore, according to our experience, even the occurrence of high levels (≥10 units) of anticardiolipin/antiphospholipid antibody in a woman with habitual abortion is not a definite reason for treatment with prednisolone and low-dose acetylsalicylic acid during pregnancy, which has been suggested.[1] Treatment should be considered in those women in whom the sera during a long period of time constantly display very elevated anticardiolipin levels preferentially concomitant with low C4 values, prolongation of activated partial thromboplastin time, and strong blocking antibody[15] (Unander AM, et al., unpublished data).

The skillful technical assistance of Mrs. Katarina Krook and Mrs. Katarina Karlén is gratefully acknowledged.

Fetal blood group determination in first-trimester pregnancy for the management of severe immunization

Humphrey H. Kanhai, M.D., Jack Bennebroek Gravenhorst, M.D., Reinoud J. Gemke, M.D., Marijke A. Overbeeke, M.S., Luigi F. Bernini, M.D., and Geoffrey C. Beverstock, M.D.

Leiden and Amsterdam, The Netherlands

The presence or absence of Rh_o (D) and Kell antigens on fetal red blood cells was determined in the first trimester of pregnancy on erythrocytes obtained by chorionic villi sampling with the use of mixed agglutination and solid phase microimmunofluorescence techniques. Pregnancies in one Kell-sensitized woman and seven severely RH-sensitized women with a poor obstetric history and a partner heterozygous for the offending antigen were examined. A conclusive diagnosis could be made in seven of the eight cases studied. (AM J OBSTET GYNECOL 1987;156:120-3.)

Key words: Rh immunization, Kell sensitization, chorionic villus sampling, first-trimester fetal blood group typing, mixed agglutination; microimmunofluorescence

The technique of chorionic villus sampling was introduced in the 1970s[1] and has become widely used for the diagnosis of genetic disorders in the first trimester of pregnancy. Apart from syncytiotrophoblast, cytotrophoblast, and connective tissue, the villous material obtained by chorionic villus sampling between the eighth and eleventh weeks of gestation contains distinct fetal vessels.[2] This offers the opportunity to study blood group antigens involved in hemolytic disease of the fetus and the newborn infant.

Erythroblastosis fetalis resulting from incompatibility of the Rh_o (D) antigen still occurs despite the introduction and wide application of anti-Rh_o (D) immune globin prophylaxis.[3] In addition, severe hemolytic disease of the newborn infant can be caused by other, so-called irregular blood group incompatibilities. To prevent adverse perinatal outcome, severely immunized patients are managed with a variety of invasive diagnostic and therapeutic procedures. In the event that the partner of such a patient is heterozygous for the blood group antigen involved, knowledge of the fetal blood group in early pregnancy permits a more rational management of the index pregnancy. If the fetus lacks the offending paternal antigen, unnecessary diagnostic and therapeutic procedures can be prevented. On the other hand, if the fetus appears to be positive, the choice can be either to terminate pregnancy or to initiate specific diagnostic and therapeutic procedures early in pregnancy. This report is part of an ongoing study investigating the expression of various blood group antigens in chorionic villus material in the first trimester of pregnancy; methodologic aspects of it have been reported on previously.[4, 5] The present report deals with the chorionic villus sampling technique used, the preparation of a cell suspension containing fetal erythrocytes, and the techniques for antigen detection in eight severely sensitized pregnancies.

Patients and methods

Patients. One woman severely immunized against the K antigen and seven women severely immunized against the Rh_o (D) antigen with a poor obstetric history and a heterozygous partner requested first-trimester fetal blood group determination. Six of them had requested termination of pregnancy unless the fetus could be shown to be negative for the blood group antigen in question. The characteristics of the eight patients are listed in Table I. Four of them had experienced at least one perinatal loss due to the blood group antagonism. The other four women had been delivered of at least one infant with severe erythroblastosis fetalis.

Chorionic villus sampling. Between the eighth and eleventh weeks of gestation, a transcervical trophoblast biopsy was taken with a flexible cannula with a diameter of 1.5 mm (Portex or KCH cannula). Under real-time ultrasound guidance, the tip of the cannula was directed to the insertion of the umbilical cord in the chorion frondosum. The obturator was withdrawn, a 20 ml syringe was attached to the catheter, and about 15

*I: Mixed agglutination technique; II: solid phase microfluorescence technique.
†No conclusive diagnosis possbile because the majority of fetal erythrocytes were damaged.

ml of suction was applied. The biopsy specimen was flushed out into a Petri dish containing heparinized saline solution. The material was immediately examined under a dissecting microscope and considered to be adequate when 20 mg (or more) of vascularized chorionic villi was obtained.

Isolation of fetal erythrocytes. Maternal tissue (mucus and decidua) was removed with a Pasteur pipette leaving the aspirate containing fluid (portion 1) and trophoblast. The trophoblast was isolated, minced, and washed in heparinized saline solution (portion 2). The minced villi were collected for culture overnight in Ham's F10 medium. After 24 hours the culture fluid was removed and examined (portion 3).

About 1 ml of each of the portions 1, 2, and 3 was stained with a fluorescent antifetal hemoglobin antiserum.[6] With phase contrast and fluorescence microscopy, fetal erythrocytes can be differentiated from maternal cells because of the intensity of their fluorescence and their larger size, thus allowing the percentage of fetal erythrocytes in the biopsy specimen to be calculated.

Determination of fetal blood group antigen. The presence of Rh_o (D)–positive erythrocytes in the biopsy material can be demonstrated by a mixed agglutination technique for the detection of a minor erythrocyte population.[7] A modification of this technique was used when dealing with Rh antigens[8]; for Kell determination we used the original technique.[7] In the presence of Rh_o (D)–positive erythrocytes, rosette formation occurs after centrifugation. The sensitivity of this technique in our application is at the level of one positive fetal erythrocyte per 1024 maternal Rh_o (D)–negative cells.[5]

At first, the mixed agglutination technique was used, but to overcome limitations of sensitivity and specificity of the mixed agglutination test, we developed a solid phase microfluorescence technique to detect the minor populations of positive erythrocytes. This technique is described in detail elsewhere[5] and allows ABO and Rh phenotypes of a minor cell population to be determined at the ratio of 1 in 4000. This microfluorescence technique was used in the last four cases of this study.

Results

Results of the eight pregnancies studied are summarized in Table II. In Case 1, 40 mg of trophoblast tissue was obtained after one sampling attempt. All three portions contained fetal red blood cells and the mixed agglutination technique showed two rosettes per 100 total red blood cells, indicating that the fetus was Rh_o (D) positive. One week after chorionic villus sampling the pregnancy was terminated by suction curettage and the presence of an Rh_o (D)–positive fetus was confirmed by both standard and mixed agglutination techniques.

In Case 2, the first chorionic villus sampling was attempted at 8 weeks of gestation. A total of 40 mg of villous tissue was obtained. Although the villi contained

several blood vessels, fewer than one fetal erythrocyte per 1000 maternal red blood cells was present in portions 1 to 3, and typing of the fetal cells was impossible. Clotting in the villous vessels was a possible cause of this failure. The chorionic villus sampling was repeated 10 days later when portion 3 contained 2% fetal erythrocytes with rosette formation in the mixed agglutination technique. This pregnancy was terminated at 11 weeks and the diagnosis was confirmed.

In Case 3, only the second chorionic villus sampling attempt produced sufficient chorionic villi but an insufficient number of fetal erythrocytes. The third attempt at 11 weeks afforded percentages of fetal erythrocytes in portions 1, 2, and 3 of 0.2%, 1.5%, and 0.2%, respectively. No rosette formation could be detected in the mixed agglutination technique, indicating an Rh_o (D)–negative fetus. After an uneventful pregnancy and spontaneous labor at term a healthy Rh_o (D)–negative female infant (3780 gm) was born.

Case 4 is the first reported case of typing for K in the first trimester of pregnancy. The first biopsy provided only 10 mg of chorionic villi and a second catheter insertion was undertaken to ensure that enough fetal erythrocytes were collected for the mixed agglutination technique. Our study had thus far shown that the K antigen cannot be detected by the microfluorescence technique.[5] This second biopsy attempt resulted in a decidual hematoma and the procedure was immediately terminated. Rosettes (0.5% to 1%) were seen in the preparations and a likely diagnosis of a K-positive fetus was made. The patient decided to continue her pregnancy and weekly plasmaphereses were started. The pregnancy was complicated by recurrent vaginal bleeding and preterm rupture of the membranes after the first intrauterine transfusion at 23 weeks. In total, four intrauterine transfusions were necessary. At 31 weeks of gestation a healthy female infant weighing 1560 gm was born by elective cesarean section. The neonatal period was uneventful apart from the need for several blood transfusions. In Case 5, 60 mg of chorionic villi was obtained after one sampling attempt. In portion 2, which contained 2% fetal erythrocytes, no rosettes were detected in the mixed agglutination test. Microfluorescence revealed no reaction with anti–Rh_o (D) or anti–Rh_o (E), indicating that the fetus was Rh_o (D) and Rh_o (E) negative. The patient was referred to her obstetrician at a district hospital near her home. After an uneventful pregnancy and induction of labor at 39 weeks of gestation, a healthy Rh_o (D)– and Rh_o (E)–negative male infant weighing 3460 gm was born.

In Case 6, chorionic villus sampling was technically difficult and resulted in 5 mg of villi after four attempts. Although the percentage of fetal erythrocytes was 0.8%, a conclusive diagnosis was impossible (Table II). The patient refused further chorionic villus sampling attempts. Her pregnancy was uneventful. At term she was delivered of a healthy Rh_o (D)–negative male infant weighing 3525 gm.

In Case 7, two biopsy attempts provided 25 mg of villous material. Both the mixed agglutination and the immunofluorescence tests were positive for anti-Rh_o (D) and the microfluorescence technique also was positive for anti–Rh_o (C). This patient decided to terminate the pregnancy and the results were confirmed in the abortion material.

In Case 8, one biopsy attempt produced 60 mg of tissue with 1% fetal erythrocytes in portions 1, 2, and 3. The results of both the mixed agglutination and the microfluorescence techniques indicated that the fetus was Rh_o (D) positive. This patient decided to continue her pregnancy and weekly plasmaphereses were started. After three intrauterine transfusions labor was induced at 35 weeks of gestation. A healthy female infant weighing 2700 gm was born and subsequently did well.

Comment

The results of our study thus far have demonstrated the feasibility of Rh and Kell typing of fetal erythrocytes obtained by chorionic villus sampling. With a modified mixed agglutination technique[7,8] and microfluorescence,[5] a conclusion about the fetal blood group was possible in seven of the eight cases studied. In one patient the Rh_o (D) status of the fetus could not be determined, although there were 0.8% fetal erythrocytes in the chorionic villus sampling material. Chorionic villus sampling was difficult in this obese patient; although no rosettes were seen and fluorescence was negative, a conclusive diagnosis was impossible because of damaged fetal erythrocytes. However, pregnancy was uneventful and the child was Rh_o (D) negative. In the two cases in which the fetus was Rh_o (D) negative, pregnancies followed a natural course. Of the five pregnancies in which the fetus was Rh_o (D) positive, three were terminated with suction curettage with the patient under local anesthesia. In the remaining two pregnancies, plasmapheresis and intensive management were started at 10 to 11 weeks.

The laboratory techniques (mixed agglutination and microfluorescence) are based on the principle of the detection of a blood group on a minor (fetal) red blood cell population that is not present on the major (maternal) red blood cell population. As the majority of erythrocytes in all biopsy specimens are of maternal origin, only the demonstration of rosettes or fluorescence is conclusive. In cases in which there is no rosette formation and the fluorescence is negative, on the other hand, it can only be concluded that the fetus is negative for the blood group under investigation if there are an

adequate number of fetal erythrocytes in the biopsy specimen. A further chorionic villus sampling attempt can be necessary in such cases.

Determination of a fetal blood group in the first trimester of pregnancy is of great advantage for severely immunized patients with a heterozygous partner. Until recently, the antenatal determination of fetal blood group was only possible from the second trimester on by fetoscopy[9] and ultrasound-guided percutaneous needle puncture of an umbilical vessel.[10] The risks of fetal blood group determination in the first trimester by chorionic villus sampling are probably less than in second-trimester procedures. Moreover, chorionic villus sampling has the advantage that an early diagnosis is possible. However, the risks of chorionic villus sampling must also be considered. In 11,819 pregnancies (90 centers) the maximal fetal loss rate after chorionic villus sampling was 4%.[11] Since the obstetric risks of chorionic villus sampling are still not fully understood, the technique must presently be considered as an applied research procedure,[12, 13] which requires further evaluation. In our group of eight patients, one pregnancy was probably complicated as a result of the procedure. Another risk of chorionic villus sampling for this type of patient is fetomaternal transfusion resulting in an increase of antibody levels. In our group of eight patients there were two with sensitized fetuses who wished to continue their pregnancies. No significant rise in antibody levels was detected in these patients. Although chorionic villus sampling is known to cause a rise of α-fetoprotein in a significant number of patients, this is by no means conclusive evidence of fetomaternal hemorrhage.[14]

Termination of pregnancy after chorionic villus sampling when the fetus is found to be Rh_o (D) positive deserves special comment. Since anti-Rh_o (D) serum does not exist, the likelihood that a subject is heterozygous for Rh_o (D) can be estimated only after the rhesus phenotype has been determined.[15] This implies a chance of error in the estimation of heterozygosity for Rh_o (D). Other diagnostic tools, such as the obstetric history and phenotyping of sibs of the partner, are important for a more definitive conclusion concerning the paternal genotype.

When all these considerations are taken into account, chorionic villus sampling for fetal blood group typing must be reserved for a highly selected group of patients, who will require detailed follow-up. Good counseling before pregnancy remains of paramount importance.

Our thanks are due to Mr. R. J. Meerman for expert ultrasonic assistance and to Prof. C. P. Engelfriet and Prof. M. J. N. C. Keirse for their support.

Chorionic biopsy in management of severe Kell alloimmunization

F. Rodesch, M.D., M. Lambermont, M.Sc., C. Donner, M.D., Ph. Simon, M.D., F. Romasco, B.S., J. Schwers, M.D., and J. Wybran, M.D.

Brussels, Belgium

Determination of fetal red blood cell Kell antigen is possible on fetal red blood cells obtained at 10 weeks of gestation by chorionic biopsy and may contribute to the management of severe Kell-hemolytic disease. (AM J OBSTET GYNECOL 1987;156:124-5.)

Key words: Chorionic biopsy, Kell antigen, hemolytic disease

As has been shown for Rh_0 (D) immunization,[1] it would be of great help for severely immunized women with anti-Kell antibodies and with a partner heterozygous for Kell antigen to have the fetal Kell antigen status determined in early pregnancy.

A chorionic biopsy was performed before termination of pregnancy. The cell suspension obtained after mincing of the chorionic villi collected by aspiration with a syringe through a Portex catheter reliably contained, as shown by the Kleihauer test, 1% fetal red blood cells among the maternal red blood cells. An immunogold silver staining technique as previously described[2] was used for the demonstration of the Kell antigen. Briefly, this technique was performed on a 2% red blood cell suspension and successively used an anti-Kell serum, a rabbit antihuman immunoglobulin G serum, and a colloidal gold–labeled goat antirabbit serum, followed by silver sensitization. The developed cytocentrifuged preparations were counterstained with standard May-Grünwald Giemsa stain and examined under a light microscope. As many of the fetal red blood cells were erythroblasts, they were easily identified. A positive control consisting of a suspension of 1% Kell-positive red blood cells among Kell-negative red blood cells was observed. The Kell-positive cells were heavily coated with gold-silver particles whereas Kell-negative cells had no such particles on their surfaces. We also demonstrated by this technique Kell antigen on fetal red blood cells obtained by chorionic biopsy before termination of a 9 weeks' gestation from a Kell-positive mother.

Case report

A 29-year-old woman, gravida 3, para 2, who had never received a blood transfusion, was referred because of fetal death early in the third trimester in her two previous pregnancies. After the second delivery, a Kell hemolytic disease was suggested by a high maternal anti-Kell titer (Coombs 1/1000). The phenotype of the patient and her husband were established, being ccdee, kk and CCDee, Kk, respectively. We discussed with these parents who were facing a pregnancy with a risk of severe Kell-hemolytic disease (the father being heterozygous for the Kell antigen), the possibility of fetal red blood cell Kell antigen determination. Termination of pregnancy if the fetus appeared to be Kell positive was offered as an alternative to difficult and uncertain fetal management. With the immunogold silver staining technique described,[2] we were able to demonstrate that the fetal red blood cells collected at 10 weeks of gestation by chorionic biopsy did not possess the Kell antigen. The maternal anti-Kell titer was high (1/2000). At 24 weeks of gestation a pure fetal blood sample (3 ml) was obtained by direct puncture of the umbilical cord with a 21-gauge needle under ultrasound guidance. The phenotype of the fetal red blood cells was shown by standard agglutination methods to be O, CcDee, kk, thus confirming our previous finding in fetal red blood cells at 10 weeks. The direct Coombs test was negative. A 3760 gm healthy female infant was delivered after spontaneous labor at 38 weeks' gestation. The direct Coombs test was negative and the fetal phenotype O, CcDee, kk was confirmed in the cord blood.

Comment

This is the first report of Kell antigen demonstration on fetal red blood cells obtained by chorionic biopsy in the first trimester of pregnancy. For couples facing a high-risk pregnancy because of Kell hemolytic disease, abortion of a Kell-positive fetus could be an alternative to difficult and uncertain management. On the contrary early demonstration of a kk fetal phenotype would relieve anxiety and prevent unnecessary later diagnostic procedures.

Spontaneous rupture of the membranes, functional dystocia, oxytocin treatment, and the route of delivery

Joseph Seitchik, M.D., Alan E. C. Holden, M.A., and Maria Castillo, R.N.
San Antonio, Texas

The details of clinical management were examined in 96 nulliparous patients with functional dystocia who had spontaneous rupture of the membranes before admission and were treated with oxytocin in the first stage of labor. It was our hypothesis that if the allegedly "high" rate of cesarean sections was the result of mediocre or flawed practices, these should be most evident in patients delivered abdominally. A group of 59 patients delivered vaginally were compared with 37 patients delivered by cesarean section. The means of many variables were not statistically different. The cesarean section group was characterized by smaller stature, a lesser cervical dilatation rate both before and after oxytocin administration, a larger maximum oxytocin dose, a longer period of oxytocin administration, more frequent cessation of oxytocin administration or dose reduction because of hypercontractility or an abnormal fetal heart rate or both, and a higher incidence of intra-amniotic infection. We conclude that the decision to perform cesarean section in nulliparous women with functional dystocia arises from disabilities of the patient and not from differences in the application of our management principles, services, or treatments. (Am J Obstet Gynecol 1987;156:125-30.)

Key words: Spontaneous membrane rupture, oxytocin, functional dystocia, cesarean section

In a previous study of patients with intact membranes and functional dystocia, we demonstrated that the application of our diagnostic and therapeutic concepts and techniques was no different in the patients who were delivered by cesarean section or vaginally.[1] We concluded that these modern management principles are not contributors to the increased rate of abdominal delivery. In this study, the same question was asked concerning patients with spontaneous rupture of the membranes before hospital admission and who had spontaneous labor: Were the diagnostic and therapeutic practices different in the groups of patients delivered vaginally and abdominally?

Methods

Study patients were selected in the following manner. During the approximate year from April 1, 1983, to March 10, 1984, 300 consecutive cesarean sections were

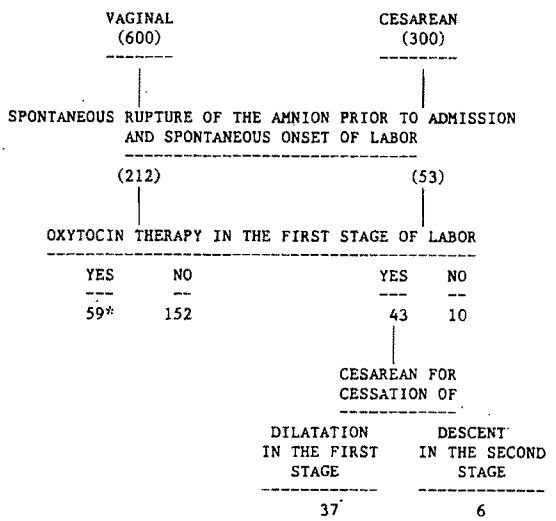

Fig. 1. The plan of the study. Three hundred patients delivered abdominally of a singleton fetus formed the cesarean section group. The first nulliparous patient delivered vaginally of a singleton fetus just before and the first delivered just after the cesarean section formed the vaginal delivery group (N = 600). The 59 patients with spontaneous rupture of the membranes and oxytocin therapy who were delivered vaginally were compared with the 37 patients with failure to achieve complete dilatation and who were delivered abdominally. *Asterisk*, One patient with extensive missing data was excluded.

performed in nulliparous patients with singleton fetuses. The last nulliparous woman who was delivered vaginally just before each cesarean section and the first who was delivered just afterward composed the control group (Fig. 1). There were 265 patients who experienced spontaneous rupture of the membranes and spontaneous onset of labor. Of the 212 who were delivered vaginally, 60 of 212 (28%) required oxytocin. One of the 60 patients had so little information recorded that her data were removed from the vaginal delivery group, with 59 patients remaining in that set. Of the 53 patients who were delivered by cesarean section, 43 of 53 (81%) received oxytocin. Failure to attain complete dilatation was observed in 37 of 43 (86%) and these 37 cases formed the cesarean section group. The Statistical Package for the Social Sciences was used for data analysis,[2] and the statistical methods included χ^2, two-tailed Student's *t* test, one-way analysis of variance, and multiple regression. Faculty members of the Department of Obstetrics and Gynecology and obstetric and family practice residents served as the attending physicians. The decision to use oxytocin was the judgment of senior obstetric residents or faculty; the choice of cesarean section was the prerogative of the faculty; the interim care was provided by junior residents. No specific oxytocin regimen was used; any dosage schedule recommended in textbooks or peer-reviewed journals was acceptable.

Results

The only significant differences at admission between the abdominal and vaginal delivery groups as to the decision to start oxytocin were in the heights of the patients and the mean cervical dilatation rates (Table I). The elapsed mean duration of time from admission to complete dilatation (vaginal group) or to the decision for cesarean section was grossly longer in the group delivered abdominally (Table II). This result obtained because the cesarean section patients averaged 5 more hours (7.8 versus 2.8) from the start of oxytocin to the final dose change. The other time segments of the patients' stay in the labor suite—from admission to the decision for oxytocin, from the decision for oxytocin to its start, or from the last dose change to complete dilatation (vaginal group) or to the decision for cesarean section—were similar. This prolonged period of dose selection in the cesarean section group was associated with a significantly higher mean maximum dose and a greater incidence of stopping or reducing the dose. The rate of incrementation of the oxytocin dose was similar in both groups, as was the frequency of operative delivery associated with abnormal fetal heart rate, birth weight, and 5-minute Apgar score. The incidence of intra-amniotic infection diagnosed during labor was three times greater in the cesarean section group ($p < 0.01$).

Both groups were examined at similar intervals after the start of oxytocin (Table III). The vaginal delivery group manifested a significantly greater mean dilatation rate at each sequential examination, but the large standard deviations indicate that some patients had rapid dilatation and others little, if any. The patients destined to be delivered vaginally had full dilatation at a faster rate than the decision for abdominal delivery was reached in the cesarean section group. Almost two thirds of the vaginal delivery group had full dilatation by an average of 7.3 hours, but the decision for operative delivery had been made by a mean of 8.4 hours in only about one fifth of the cesarean section patients.

Once functional dystocia was diagnosed and the decision to use oxytocin made, the remainder of the labor room stay of the patients undergoing cesarean section was composed mainly of the period from the start of oxytocin to the last dose change (an average of 7.8 of

10.9 hours). It is logical to assume that the major cause of variance in the duration of this "dose-finding" period would be the maximum dose of oxytocin administered. When the data for this variable were segmented into four class intervals (<x − 1 SD, x − 1 SD to x, x to x + 1 SD, >x + 1 SD), one-way analysis of variance demonstrated that the maximum dose of oxytocin was the only variable with a value that fluctuated significantly with the duration of the several class intervals of the "dose-finding" period (Table IV). Multiple regression analysis demonstrated that 77% ($R^2 = 0.77$, $p < 0.001$) of the "dose-finding" time variance can be accounted for. Fluctuations in the values for the maximum dose were responsible for 72% of the explained variance; the presence of preeclampsia and the use of magnesium sulfate and stopping or reducing the dose played minor additional roles. With either method of analysis, it is clear that the maximum dose of oxytocin was the major determinant of the length of the "dose-finding" period, which, in turn, was responsible for the duration of the patients' labor room stay once the diagnosis of functional dystocia and the decision to use oxytocin were made.

In contrast, for the vaginal delivery patients, the "dose-finding" period occupied less than half of the patients' time in the labor suite from the decision to use oxytocin to complete dilatation (an average of 2.8 of 6.1 hours). Segmenting the data by the same four class intervals of the "dose-finding" period and use of one-way analysis of variance revealed that the values

for the maximum dose of oxytocin, stopping or reducing the dose, and cervical dilatation fluctuated significantly (Table IV). Multiple regression demonstrated that 59% of the variance in the "dose-finding" period could be explained ($r = 0.59$, $p < 0.001$). Stopping or reducing the dose and the interactions of that variable accounted for 58% of the explained variance, whereas the maximum dose of oxytocin and its interactions explained 35%. We interpret these data to suggest that when the range of maximum doses for most patients was small, as in the vaginal delivery group, factors other than dose tended to be more important in the determination of the length of the "dose-finding" period.

Comment

Our observations indicated that the need for abdominal delivery was not an artifact created by our practices. Patients destined for cesarean section were given larger doses of oxytocin during longer periods of time and, once the selected maximum dose was administered, were observed for a period of time similar to that required by the vaginal delivery patients to reach full dilatation. Smaller stature and intra-amniotic infection diagnosed before delivery occurred more frequently in the cesarean section group.

Comparison of patients with functional dystocia admitted with ruptured membranes with those experiencing amniotomy suggests that, in our experience, the groups were not identical (Table V). Regardless of mode of delivery, at admission the group with spontaneous rupture of the membranes had fewer patients with preeclampsia treated with magnesium sulfate but more having poor contractile activity and less cervical dilatation and longer stays in the labor suite until complete dilatation or the decision for cesarean section. The difference in the mean duration of the labor room experience for patients delivered vaginally was the result of a significantly longer time for the patients with spontaneous rupture of the membranes between admission and the decision to use oxytocin ($p < 0.001$). The combinations of lesser cervical dilatation and contraction frequency and fewer patients with preeclampsia probably account for this difference.

Little cervical dilatation and infrequent or no contractions always engender the question, "Is the patient in labor?" In nulliparous women, we can avoid induction of labor with its attendant high cesarean section rate by observation of the patient during a period of time. In the absence of any compelling indication for delivery, such as preeclampsia, we found no contraindication to waiting for contractions to appear in patients who had none or for contractions to improve, persist, or disappear in those who had them infrequently. On our service, the rate of cesarean section because of failure to achieve complete dilatation among nulliparous women with spontaneous labor and oxytocin therapy for functional dystocia is 13% for those with amniotomy and 16% for those with spontaneous rupture of the membranes, a nonsignificant difference. This policy, which insists that contractions be present and persist before the diagnosis of labor is accepted, has not contributed to the frequency of abdominal delivery.

Alternatively it seems unreasonable to insist that the diagnosis of labor requires some observed change in cervical dilatation once the membranes are ruptured, spontaneously or artificially. Regardless of the mechanism of rupture of the amnion or the route of delivery, approximately 25% of each group failed to demonstrate a change in cervical dilatation of ≥ 1 cm from admission to the decision for oxytocin (Table V). Our avoidance of the requirement that some significant change in dilatation occur in each and every patient before the diagnosis of labor and functional dystocia was entertained did not appear to contribute to the frequency of cesarean section. If we were incorrect in this judgment, then the percentage of patients with no cervical dilatation from admission to the decision to use oxytocin would have been significantly greater in the patients delivered abdominally.

It is common wisdom that the longer the labor, the higher the incidence of intra-amniotic infection. For the patients with spontaneous rupture of the membranes, the mean duration from admission to the decision for cesarean section was 19.1 hours. The diagnosis of intra-amniotic infection before delivery was made in 14 (38%) patients and was present in only one case at admission, becoming manifest in the other 13 during labor. What potential do we have for reducing the length of labor? We suggest two possibilities. The mean time from admission to the use of oxytocin might be reduced if, once the diagnosis of labor is made, we

insist that each patient manifest a detectable change in dilatation in each 2-hour period.[1] If not, appropriate therapy should be accomplished promptly. This management principle requires omitting the concept of a latent phase of first-stage labor from our evaluation of these patients. The second opportunity may exist in the "dose-finding" period. The use of regimens that rapidly increment the dose and their resultant large maximum doses can produce hypercontractility and deviations from fetal heart rate norms. These events, most evident in patients monitored by electronic devices, cause the oxytocin to be stopped or the dose reduced frequently in patients destined for cesarean section. As a result, the process of finding the needed dose becomes inefficient. The use of regimens designed from the knowledge that (1) any specific dose of oxytocin requires about 40 minutes to reach a steady-state plasma concentration and (2) 70% to 75% of the patients with functional dystocia will need a dose of ≤4 mU/m and 95%, ≤9 mU/m may reduce the length of the "dose-finding" time.[4,5]

Polyhydramnios and elevated intrauterine pressure during amnioinfusion

Bannie L. Tabor, M.D., and Jeffrey A. Maier, M.D.
Torrance, California

Amnioinfusion has been demonstrated to be useful in relieving and preventing repetitive variable decelerations. There have been no reported complications. This case illustrates the potential for iatrogenic polyhydramnios and elevated intrauterine pressure during amnioinfusion. (AM J OBSTET GYNECOL 1987; 156:130-1.)

Key words: Amnioinfusion, polyhydramnios, elevated intrauterine pressure

Saline amnioinfusion has been demonstrated to be effective in preventing and relieving repetitive variable decelerations. This results in a lower cesarean section rate for fetal distress in nulliparous patients[1] and in an improved metabolic state in infants of patients with preterm premature rupture of the membranes.[2] There have been no reported complications with this procedure.

We report a case that shows that in certain situations the procedure is not without risk.

Case report

A 21-year-old woman, gravida 3, para 1, at 34⅘ weeks' gestation, presented with a 4½-hour history of spontaneous rupture of the membranes without uterine contractions. A sterile speculum examination confirmed ruptured membranes. The cervix appeared long and closed. Adequate amniotic fluid was noted on ultrasound examination. An oxytocin induction of labor was started. Amniotic fluid continued to leak during the next 24 hours as the cervical examination revealed progression to 2 cm dilation, 50% effacement, and −1 station. A repeat ultrasound examination showed decreased amniotic fluid, the largest pocket measuring <2 cm vertically. The patient was randomized to receive amnioinfusion in an ongoing approved human subjects protocol.

The intrauterine pressure was 10 mm Hg before the amnioinfusion. A total of 600 ml of normal saline solution was infused during 1 hour by an intermittent infusion pump through an attachment to the internal

uterine catheter. The resting intrauterine pressure increased to 15 mm Hg. A maintenance rate of 180 ml/hr was then begun; 2700 ml of fluid was infused during the next 15 hours accompanied by an increase in the uterine pressure to 20 mm Hg. Modest vaginal leakage was noted.

An additional liter of fluid was infused during the next 5 hours without vaginal leakage. The intrauterine baseline pressure gradually increased to 50 mm Hg. The fetus then had two prolonged decelerations, followed by a 6-minute bradycardiac episode to 70 bpm. This was relieved by stopping the oxytocin, changing the patient's position, and administering tocolysis with terbutaline, 0.25 mg subcutaneously. The patient complained of constant abdominal pain. On examination the uterus was very tense and tender. The cervix was 2 cm dilated, 70% effaced, and at −1 station. The amnioinfusion was halted. The resting pressure remained elevated at 45 mm Hg. Ultrasound examination revealed marked polyhydramnios, the fluid pocket measuring >10 cm vertically. Uterine contractions returned and were associated with repetitive moderate variable decelerations. These were relieved by draining 150 ml of amniotic fluid; an additional 750 ml of fluid was drained before the pressure returned to normal (15 to 20 mm Hg). Thereafter the fetal heart rate was 155 bpm with good variability and reactivity. The uterus was soft and nontender between contractions.

Oxytocin was restarted, and the patient was ultimately delivered of a 2350 gm male infant with Apgar scores of 7 at 1 minute and 8 at 5 minutes. The umbilical arterial pH was 7.23 and the venous pH was 7.35. There was no nuchal cord or any other cord abnormalities. Before delivery the patient developed amnionitis and was placed on a regimen of ampicillin, which was continued post partum. Her postpartum course was uncomplicated. The infant initially exhibited mild diffuse hypotonia, which spontaneously resolved. He was treated with antibiotics until all cultures were returned negative. A subgaleal hematoma was noted and was felt to be due to the prolonged course of labor. He was discharged on day 7, doing well and without sequelae.

Comment

In previously reported studies there has been no mention of significantly increased intrauterine pressure or polyhydramnios with amnioinfusion. Miyazaki and Nevarez[1] reported an increase in the resting pressure to 35 to 40 mm Hg during the gravity-driven bolus infusion, which was artifactual. In a personal communication, Nageotte also related an increase in baseline pressure during prophylactic amnioinfusion. Our protocol is similar to Nageotte's, in that the fluid is actively infused by a mechanical pump. Due to the pulsatile action of the pump, the tokodynamometer records a compact sine wave because of the increased pressure in the catheter as the pump infuses. The true intrauterine pressure coincides with the wave trough and can be confirmed by closing the connection between the pump and the intrauterine catheter.

With both techniques fluid is infused under pressure, be it mechanical pressure from the pump or hydrostatic pressure from the column of water in the gravity infusion system. This has little deleterious effect in most cases as the fluid is infused into an open system. As labor progresses, there is space between the dilating cervix and the fetal presenting part, which allows fluid and pressure to escape.

In the reported case, the fetal head was firmly applied to the cervix, thus creating a closed system. The pump continued to infuse fluid, resulting in polyhydramnios and eventually a significant increase in intrauterine pressure. This could arise with the use of either method as both have the potential for infusing fluid under pressure. The precise pathophysiologic mechanism of the associated fetal heart rate decelerations is unclear. We speculate that the increased intrauterine pressure prevented adequate uteroplacental perfusion.

This situation can be avoided by carefully monitoring the true intrauterine pressure during amnioinfusion and regularly assessing the amount of amniotic fluid by ultrasound. Maintaining these within normal limits should prevent fetal compromise in this otherwise safe procedure.

Screening for gestational diabetes: One-hour carbohydrate tolerance test performed by a virtually tasteless polymer of glucose

E. Albert Reece, M.D., Theodore Holford, Ph.D., Susan Tuck, M.D., Mitzi Bargar, R.N., Theresa O'Connor, M.P.H., and John C. Hobbins, M.D.

New Haven, Connecticut

Although the 1-hour 50 gm blood glucose screening test is an effective way of detecting diabetes in pregnancy, the taste of available glucose drinks often creates gastrointestinal symptoms and leads to refusal of the patient to be tested. The efficacy of a virtually tasteless glucose polymer in testing carbohydrate tolerance in pregnancy was determined. Sixty-one pregnant patients undergoing screening for gestational diabetes underwent a 1-hour carbohydrate tolerance test of both glucose and a glucose polymer within 3 days of each other. Analysis of the data revealed a high degree of agreement between the results of the 1-hour carbohydrate tolerance test ($\kappa = 0.62$, $p < 0.0001$). These data suggest that glucose polymer can be used effectively in screening for gestational diabetes. (AM J OBSTET GYNECOL 1987;156:132-4.)

Key words: Carbohydrate tolerance, Polycose

It is well established that pregnancy has a diabetogenic effect, and the glucose intolerance that develops in pregnancy can be associated with an increase in perinatal mortality.[1, 2] The oral glucose tolerance test has become the recommended method to assess carbohydrate metabolism in pregnancy.[3-6] O'Sullivan et al.[5] have demonstrated that a 1-hour 50 gm blood glucose screening test followed by a 3-hour glucose tolerance test, performed in those patients with a blood glucose level exceeding 130 mg/dl of whole blood, is an effective way of identifying potentially diabetic patients. However, glucose drinks currently available are often associated with nausea, vomiting, abdominal bloating, or even headache.[6] Noncompliance and vomiting will render these blood studies meaningless.

Glucose polymer (Polycose*) is a commercially available, inexpensive glucose saccharide mixture that is virtually tasteless and contains 3% glucose, 7% maltose, 5% maltotriose, and 85% polysaccharides of 4 to 15 (mean = 5) glucose units.[7] Its osmotic load is one fifth that of glucose and has been reported to be associated with less gastrointestinal symptoms.[7] The purpose of this study is to determine whether this glucose polymer could be effectively used in a 1-hour carbohydrate tolerance test to screen for gestational diabetes.

Patients and methods

Patients undergoing diabetes screening were invited to participate in a study where glucose was compared with a glucose polymer in the performance of a carbohydrate tolerance test. Patients were instructed to maintain a 300 gm carbohydrate-enriched diet for 2 to 3 days before the study in order to maximize and standardize the carbohydrate tolerance tests.[8] Patients fasted overnight, and on the morning of the test whole blood determinations of fasting blood sugar were obtained, followed by the ingestion of a 50 gm drink of glucose polymer. A blood glucose level was obtained 1 hour later. Glucose determination was performed by the enzymatic reaction with the use of glucose oxidase as described elsewhere.[9, 10] A repeat test with the standard glucose drink was performed in all patients within 3 days of the first study. Patients were asked to comment on the taste and to report any symptoms, including nausea or vomiting, that they experienced. Patients were not charged for these tests; however, the approximate cost of a 50 gm Polycose drink was 35 cents, compared with the $2.50 cost of a standard 50 gm glucose drink. Normal values used for both tests were those reported by O'Sullivan et al.[5] for glucose. Patients underwent a 3-hour glucose tolerance test if at least one study (glucose or Polycose) was abnormal. In order to determine whether the two test results were equivalent, the data were analyzed with the use of the κ statistic, $\kappa = Po-Pc/1-Pc$, where Po = proportion of observed agreement and Pc = overall proportion of

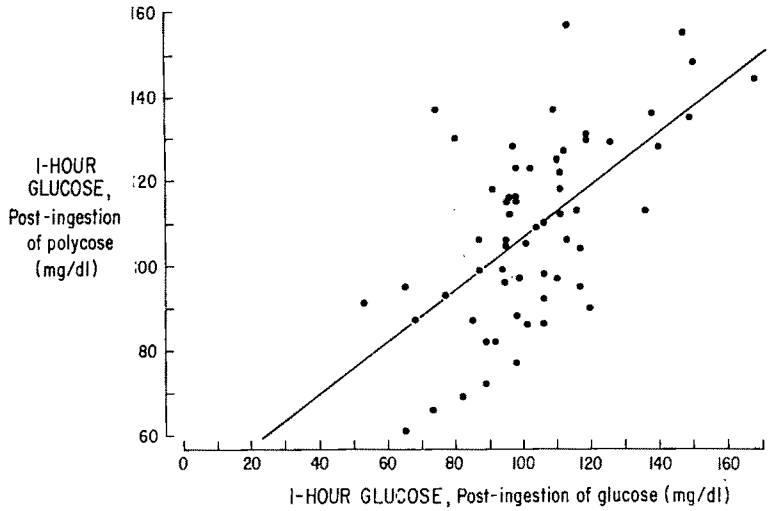

Fig. 1. Scatter plot of 1-hour glucose values after ingestion of glucose polymer (y axis) and glucose (x axis).

Table I. Results of 1-hour carbohydrate tolerance test

Result of glucose test	*Results of Polycose test*			
	Negative		*Positive*	
	n	%	*n*	%
Negative	51	83.6	3	4.9
Positive	2	3.3	5	8.2

$\kappa = 0.62$; $p < 0.0001$.

agreement expected by chance alone. The κ statistic is a measure of the amount of agreement between the two tests beyond that expected by chance alone. A κ statistic <0 indicates less than chance agreement; $\kappa = 0$ indicates just chance agreement; $\kappa > 0$ indicates more than chance agreement; and $\kappa = 1$ indicates perfect agreement.[6]

Results

Sixty-one patients underwent a 1-hour carbohydrate tolerance test with both Polycose and glucose. Of these, 51 (83.6%) had normal results in both tests, five (8.2%) were abnormal in both studies, and in five patients (8.2%) one of the two studies was abnormal (Table I). Although the mean blood glucose levels at fasting in both the Polycose and glucose groups were similar to each other, at 1 hour after Polycose ingestion the blood glucose level was consistently above that observed after the glucose drink but remained well within the normal range (<120 mg/dl) (Table II). Since the false negative rate for a 1-hour glucose tolerance test is <1%, a 3-hour glucose tolerance test with the 100 gm glucose load was performed only in those patients having at least one abnormal study. The normal glucose determinations used were those outlined by O'Sullivan and Mahan.[4] The 3-hour glucose tolerance test was negative for three patients with positive Polycose and negative glucose results, and negative for two patients with negative Polycose and positive glucose results. Of the five patients with positive Polycose and positive glucose results, the 3-hour glucose tolerance test results were positive in two and negative in three. Analysis of the data revealed a high level of agreement between the results of the 1-hour carbohydrate tolerance tests ($\kappa = 0.62$; $p < 0.0001$). Fig. 1 shows a scatter plot of the 1-hour blood glucose levels for the two tests. In addition, patients expressed a greater preference for the Polycose drink than for the glucose. Unfortunately, many patients failed to complete the questionnaire completely. However, about 40% of patients experienced nausea and/or vomiting after glucose compared with about 10% after Polycose ingestion.

Table II. Blood glucose determinations of both Polycose and glucose tolerance tests

Test	*Fasting blood glucose (mg/dl, mean ± SE)*	*Blood glucose 1 hr after ingestion (mg/dl, mean ± SE)*
Polycose	66.67 ± 12.56	108.7 ± 21.9
Glucose	68.63 ± 10.36	103.4 ± 21.9

Comment

The results of this study demonstrate that carbohydrate tolerance testing can be satisfactorily performed by a glucose polymer, which is less expensive and preferred over glucose by patients. The high patient acceptance rate in our study is in agreement with a prior

report by Court et al.[7] Those investigators calculated the area under the curve (incremental area) for glucose and Polycose to determine the reproducibility of the tolerance tests. The more similar the incremental areas of paired tests were with the use of the same agent, the more reproducible the test was considered to be. The correlation between incremental areas of the paired tolerance test was not significant for glucose but was significant for glucose polymer ($p < 0.001$), thus suggesting a greater reproducibility for Polycose than glucose.[7] In our study, although 3-hour glucose tolerance tests were not done in all patients, the high degree of correlation between the 1-hour Polycose and glucose tolerance tests suggests similar true and false negative and true and false positive rates. O'Sullivan et al.[4,5] have shown that the 1-hour glucose tolerance test has a false negative rate of <1% and a false positive rate of 86%. Our studies indicate that similar rates may be presumed for the 1-hour Polycose tolerance test.

The normal metabolic changes of pregnancy produce a "diabetogenic effect," and the incidence of impaired glucose tolerance during pregnancy is about 2% to 3%.[11-13] Prospective studies have shown that perinatal morbidity and mortality are higher in women with gestational diabetes than in randomly selected control patients.[8, 11, 12] Since improved detection of gestational diabetes and more aggressive treatment have resulted in improved rates of perinatal morbidity and mortality, it is extremely important that a screening test for gestational diabetes should not only be sensitive but be acceptable to patients, so that maximal compliance can be achieved. Hoet and Beard[14] compared various screening tests in terms of sensitivity and cost and concluded that the O'Sullivan and Mahan 1-hour glucose tolerance test has the advantage of high sensitivity, acceptable specificity, and low cost. Although the advantages of this test are self-evident, the disadvantages include its taste, which often creates gastrointestinal symptoms as well as refusal of the patient to be tested.

Our comparison of carbohydrate tolerance tests with the use of both glucose and glucose polymer demonstrates striking similarities in test results but disparity in patient satisfaction and tolerance. These data suggest that glucose polymer is preferable to glucose in a 1-hour carbohydrate tolerance test to screen for gestational diabetes.

We wish to thank Nancy Nickless, R.N., Nina Tiglio, R.D., M.P.H., and Lyn Oehler, M.S., R.D., for their assistance in this study.

A CONTINUING AMA CATEGORY I MEDICAL EDUCATION PROGRAM

Postgraduate Obstetrics and Gynecology is a biweekly publication consisting of 26 lessons per year. Every two weeks during the calendar year each subscriber receives a state-of-the-art program which contains an original article focusing on a basic facet or contemporary problem and a self-test. Each article is prepared by an authority from among our distinguished editorial board or by a guest author selected by our editors. The articles are timely, authoritative, concise, and supplemented by visuals to provide clear illustrations of important details.

Each program concludes with a series of multiple choice questions which crystallize the most significant points of the article. The correct responses for each lesson are contained in the subsequent issue.

Accreditation—As an organization for continuing medical education, the University of Pennsylvania School of Medicine designates this continuing medical education activity as meeting the criteria for 1 credit hour per biweekly issue in Category 1 for Education Materials for the Physician's Recognition Award of the American Medical Association provided it has been completed according to instructions. This course has also been approved by the Americal College of Obstetricians and Gynecologists for 1 cognate per biweekly issue formal learning, as well as by the Committee on Continuing Education of the American Osteopathic Association for 1 credit hour per biweekly issue in Category 2B.

Each paid subscription is entitled to 26 CME credits and written CME certification is available upon request.

Please enter my subscription for one year (26 issues) of **Postgraduate Obstetrics & Gynecology.** I understand that my subscription will start with the issue following receipt of my payment ($160.00).

½ year subscription available—$90 for 13 issues.

For Brief Summary for OVCON-50 and OVCON-35, please see following page.
Mead Johnson

OVCON®-50

(norethindrone [1 mg] and ethinyl estradiol [0.05 mg]) tablets

OVCON®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg. or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50–80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15–34, 5/100,000; ages 35–44, 33/100,000; ages 45–49, 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female abortion. There is considerable evidence that estrogens are ineffective for these inc there is no evidence from well-controlled studies that progestins are effective for Increases in chromosomal aberrations have been reported in women who become p after ceasing oral contraceptive therapy. Embryos with these anomalies are virt spontaneously aborted. Whether there is an overall increase in spontaneous abortion o conceived soon after stopping oral contraceptives is unknown. It is recommended that f who has missed two consecutive periods, pregnancy should be ruled out before cc contraceptive regimen. If the patient has not adhered to the prescribed schedule, the pregnancy should be considered at the time of the first missed period and furthe contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is c patient should be apprised of the potential risks to the fetus and the advisability c continuation should be discussed in light of these risks. It is also recommended that discontinue oral contraceptives with the intent of becoming pregnant use an alter contraception for a period of time before attempting to conceive. Many clinicians recor months. Administration of progestin-only or progestin-estrogen combinations to induc bleeding should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies hav increased risk of surgically confirmed gallbladder disease appearing after one contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydr Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant p patients on oral contraceptives. For this reason, prediabetic and diabetic patients shoul observed while receiving oral contraceptives. Increased serum levels of triglycerid phospholipids have been observed in oral contraceptive users. The clinical signific observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood p been reported in women receiving oral contraceptives. The prevalence of hyperten contraceptive users may be no higher than nonusers in the first year of oral contracep increases with longer exposure and in the fifth year of use is two and one-half to thr reported prevalence in the first year. Women who previously had hypertension during pre be more likely to develop elevation of blood pressure when given oral contraceptives. 9) The onset or exacerbation of migraine or development of headache of a new patte recurrent, persistent or severe, requires discontinuation of oral contraceptives and inv the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as ir irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In u persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic m indicated to rule out pregnancy or malignancy. If pathology has been excluded, time c another formulation may solve the problem. Changing to an oral contraceptive with a high content, while potentially useful in minimizing menstrual irregularity, should be d necessary since this may increase the risk of thromboembolic disease. Women with a pa oligomenorrhea or secondary amenorrhea or young women without regular cycles tendency to remain anovulatory or to become amenorrheic after discontinuati contraceptives. Women with these preexisting problems should be advised of this pos encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic intrauterine pregnancy may occur in contraceptive failures. However, in oral contracept the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral cor since the drugs are more effective in preventing intrauterine rather than ectopic preg higher ectopic-intrauterine ratio has been reported with both combination products and only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal age contraceptives has been identified in the milk of mothers receiving these drugs. The effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initia contraceptives. Examination should include special reference to blood pressure, breast and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a g oral contraceptives should not be prescribed for longer than 1 year without anoth examination being performed. 2) Under the influence of estrogen-progestogen pr preexisting uterine leiomyomata may increase in size. 3) Patients with a history depression should be carefully observed and the drug discontinued if depression recurs degree. 4) Because oral contraceptives may cause some degree of fluid retention, condi might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome renal insufficiency or asthma require careful observation. 5) Patients with a past history during pregnancy have an increased risk of recurrence of jaundice while receiving oral co therapy. If jaundice develops in any patient receiving such drugs, the medication discontinued. 6) Steroid hormones may be poorly metabolized in patients with imp function and should be administered with caution in such patients. 7) Oral contraceptive have disturbances in normal tryptophan metabolism which may result in a relative deficiency. The clinical significance of this is yet to be determined. 8) Serum folate lev depressed by oral contraceptive therapy. This may complicate subsequent pregnancy wit folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy wh specimens are submitted. 10) Certain endocrine and liver function tests and blood compo be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TE to increased circulating total thyroid hormone, as measured by protein-bound iodine (I column, or T_3 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting th TBG; free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduce to metyrapone test. 11) The active yellow tablets and the inert green tablets in Ovcon-50 day regimens) and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) in the general population is low, it is frequently seen in patients who also ha hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patie been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding associated with concomitant use of rifampin. A similar association has been sugge barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, ga disease, congenital anomalies. There is evidence of an association between the following and the use of oral contraceptives, although additional confirmatory studies are needed: M thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and opti The following adverse reactions have been reported in patients receiving oral contraceptiv believed to be drug related: Nausea and/or vomiting, usually the most common adverse occur in approximately 10% or less of patients during the first cycle (other reactions, as rule, are seen much less frequently or only occasionally); gastrointestinal symptoms abdominal cramps and bloating); breakthrough bleeding; spotting; change in menst dysmenorrhea; amenorrhea during and after treatment; temporary infertility after disconti treatment; edema; chloasma or melasma which may persist; breast changes (te enlargement, and secretion); change in weight (increase or decrease); change in cervical er cervical secretion; possible diminution in lactation when given immediately postpartum; c jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental de reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (ste intolerance to contact lenses. The following adverse reactions have been reported in us contraceptives, and the association has been neither confirmed nor refuted: Premen syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like s headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of la of oral contraceptives by young children. Overdosage may cause nausea, and withdrawa may occur in females.

Increased incidence of spontaneous abortion in pregnancies complicated by maternal diabetes mellitus

Hamish W. Sutherland, M.B., Ch.B., and Colin W. Pritchard, Ph.D.
Aberdeen, Scotland

A retrospective sample of 164 pregnancies in the years 1956 to 1975 of 78 insulin-dependent diabetic women was examined to assess the extent of the risk of clinically recognizable spontaneous abortion relative to the expected risk in a comparable population. This study was done before the implementation of the policy to establish good control of maternal diabetes before conception was attempted. After control of data for pregnancy number, maternal age, and epoch, the risk of spontaneous abortion among the diabetic women was almost double the estimate of the expected risk ($p < 0.001$). (AM J OBSTET GYNECOL 1986;155:135-8.)

Key words: Insulin-dependent diabetes, clinically recognizable abortion, pathogenesis of abortion

In women with insulin-dependent diabetes mellitus the loss of viable fetuses has diminished coincident with the application of improved control of maternal glycemia throughout pregnancy, although it is not possible to separate the effects of improved control from the "secular trend"[1] and the evolution of modern obstetric care.

With the introduction of a similar approach of good control immediately before conception and during embryogenesis the fetal malformation rate also has been significantly reduced.[2]

Although there are some reports that suggest that the frequency of spontaneous abortion in women with insulin-dependent diabetes mellitus is similar to that observed in the general population,[3, 4] the difficulties in obtaining good control data have engendered circumspection.[5] Without reliable information about the population from which the relative risk of abortion for women with insulin-dependent diabetes mellitus could be quantified, the potential effects of prepregnancy care (including improved metabolic control for these women) on their abortion rate remains open to doubt.

The aim of this study is to evaluate the risk of clinically recognizable abortion in women with insulin-dependent diabetes mellitus compared to the risk in the population of the same area who were subject to the same secular trend in the period before the introduction of a program of planned pregnancy for women with diabetes mellitus.

Material and methods

Spontaneous abortion refers in the United Kingdom to pregnancy failures before the twenty-eighth completed week of gestation.

Before, during, and since the period of this study it has been basic policy in the Grampian area of Scotland to admit to the hospital all women with inevitable, missed, and incomplete abortion for evacuation of the uterus under anesthesia whether or not there is coincidental disease. The diagnosis of complete abortion is rarely made and usually only following retrospective appraisal of the evidence for pregnancy and histopathologic evidence from the curettage.

The analysis reported in this paper is based on a sample of the 78 Caucasian women with insulin-dependent diabetes mellitus for whom records were available from the Aberdeen Diabetic Clinic and who had known pregnancies while insulin dependent in the years 1956 to 1975. In general terms the mode of control of the diabetes was dietary regulation and twice daily long- and short-acting insulin administration with dose adjustment according to a sliding scale of insulin dosage dependent on frequent urine test results with Clinitest tablets (Ames Co., Elkhart, Indiana). After 1975 a more active policy of blood glucose self-monitoring and prepregnancy counseling has been pursued, and the findings presented here will form the basis for part of the assessment of that policy at a later date.

Over the 20-year period under consideration these women had a total of 164 pregnancies. This represents by far the majority of pregnancies to women with insulin-dependent diabetes mellitus in the area over that period because apart from the Aberdeen center, there

Table I. Pregnancy numbers of the sample of diabetic pregnancies by previous pregnancies included in the sample

Pregnancy number	*Previous pregnancies included*							*Total*

All	28	136	164	17.07	8.84
Gestation >9 weeks	25	136	161	15.53	8.26

were no other facilities for diabetic pregnant women, public or private, in the Grampian area. Table I reports the pregnancy numbers of the sample according to the number of previous pregnancies included in the study. The sample includes the seventh pregnancy to one woman (which resulted in a live birth) who had had six previous live births. The sample includes three women who had two spontaneous abortions. In each of these cases it was the first and second pregnancies that ended in this way and the pregnancies continued beyond the ninth week of gestation.

Estimates for the "expected" incidence of spontaneous abortion were derived in the manner described below from data stored on the Aberdeen Maternal and Neonatal Data Bank,[6] which contains records of pregnancies occurring in Aberdeen dating back to 1950.

The question being asked is whether the incidence of spontaneous abortion among women with insulin-dependent diabetes mellitus differs significantly from that in the population from which they were drawn.

Given that the sample of pregnancies in women with insulin-dependent diabetes mellitus is heterogenous by age, pregnancy number, and year of pregnancy, equivalent population estimates of the incidence of spontaneous abortion are problematic. For this reason the expected incidence was derived in the following way: For each diabetic pregnancy the probability of spontaneous abortion was calculated for women of the same pregnancy number, age group (ages grouped as 16 to 19, 20 to 24, 25 to 29, 30 to 34, and 35+ years), and epoch (years grouped as 1956 to 1960, 1961 to 1965, 1966 to 1970, and 1971 to 1975) who had known pregnancies in Aberdeen. The average of these probabilities thus represents an overall probability of spontaneous abortion for a sample similar in pregnancy number, age group, and epoch composition to the sample of diabetic pregnancies.

Because of the possibility that spontaneous abortions in the early weeks of gestation were more likely to be reported among the diabetic group, this procedure was repeated excluding the three pregnancies to women with insulin-dependent diabetes mellitus which were lost before the tenth week of gestation and excluding spontaneous abortions before the tenth week of gestation in the estimation of the expected incidence.

Results

The numbers of spontaneous abortions, births, and the expected incidences are reported in Table II.

Using the χ^2 approximation to binomial probabilities to test the difference in the proportions, the probability of spontaneous abortion among the sample of pregnancies to insulin-dependent diabetic women is significantly greater ($p < 0.001$) than the expected estimate both for all the pregnancies ($\chi^2 = 12.79$) and for those continuing beyond the ninth week of gestation ($\chi^2 = 10.28$).

It is possible that the spontaneous abortions that occurred among the sample of diabetic women happened in pregnancy number by age group by epoch categories where the estimated probability of spontaneous abortion was greater than for the overall sample. The average estimated incidence of spontaneous abortions for those cells in which an abortion occurred in the diabetic

sample was 7.32%, or less than the overall estimate. Moreover, 18 of the 25 abortions (72.0%) occurring after the ninth week of pregnancy were in cells in which the incidence of spontaneous abortion was less than the overall estimate, which may be compared to 96 of the total of 161 (59.6%) in which the estimated incidence was less than the average estimated incidence.

To ensure that the finding of an increased risk of spontaneous abortion was not overestimated because of the independent effects of previous obstetric history, an analysis of the 71 first pregnancies in the sample was conducted. Eleven (15.49%) of those pregnancies ended in a spontaneous abortion. The risk was significantly greater ($\chi^2 = 4.32$; $p < 0.005$) than the population estimate of 8.07%.

The conclusion reached is that there was a significantly higher incidence of spontaneous abortion among the sample of women with insulin-dependent diabetes mellitus than would be expected on the basis of an estimate of the incidence in an equivalent sample of Aberdeen pregnancies.

Comment

Contrary to the conclusions of several previous published studies, analysis of these data show that there is a significantly increased risk of spontaneous abortion as a recognizable clinical event in women with insulin-dependent diabetes mellitus. It confirms the conclusions of Miodovnik et al.[7] in Cincinnati whose work in turn confirmed our preliminary findings.[8] In our population the increased risk for women with insulin-dependent diabetes mellitus is of the order of twofold in both first and later pregnancies, but this is far short of the overall spontaneous abortion rate of 30% in the Ohio diabetic women.[7]

The pathogenesis of abortion in women with insulin-dependent diabetes mellitus is unknown. Diabetic ketoacidosis is a rare event at such an early stage of pregnancy when hypoglycemia is much more commonly the form of metabolic derangement necessitating hospital admission.[9] Nonetheless, glycosylated hemoglobin levels are higher at the time of first booking at the prenatal clinic in the diabetic women who later abort than in those who deliver successfully.[10] Immunologic studies have characterized alterations in the fetomaternal relationship in diabetic pregnancy, but to our knowledge these have not been correlated with the degree of metabolic control in early pregnancy.[11] Maternal diabetes was the first condition in which early growth delay of the human embryo was detected by ultrasonic examination.[12] Initial growth delay is particularly evident in cases where the fetus is found later to be malformed,[13] and this has been shown to be associated with poor control of the maternal diabetes at the time of conception.[14] However, in women with insulin-dependent diabetes mellitus not all fetuses with initial growth delay are malformed or are aborted. The association of threatened abortion with initial growth delay measured by ultrasound in nondiabetic women has been reported, and the extent of the growth delay was found to relate to the risk of spontaneous abortion.[15] There is some indirect evidence that marked growth delay in the presence of maternal diabetes may cause very early abortion.[16] Unfortunately, data were not available concerning either the precise gestational age at abortion (since the proportion with missed abortion is unknown) or the incidence of fetal malformation in the aborted fetuses in this study. It was also not possible to assess the degree of maternal control of glycemia at the time preceding abortion, and no similar data exist from those in the sample who did not abort.

An advantage resulting from preconception management of women with insulin-dependent diabetes mellitus will be the facility for retrospective appraisal of blood glucose self-monitoring during the early weeks of the first trimester in diabetic women who do and do not abort. This may provide information useful in the assessment of the role of maternal glycemia in spontaneous and missed abortion in diabetic women. The effect of good maternal periconception control of diabetes on the risk of abortion requires evaluation.

The data in this study collected before such a policy was implemented in Aberdeen indicate that the clinical event of spontaneous abortion is approximately twice as likely to occur in insulin-dependent diabetic women as in a matched population control. This is based on a risk of clinically apparent spontaneous abortion in diabetic women of around 15% which is much less than the 26% and 30% found in Birmingham, England,[10] and Cincinnati,[7] respectively, where the potential for improvement in prognosis for the pregnancies of diabetic women is even more substantial and challenging.

Immunohistochemical studies on collagen types in the uterine cervix in pregnant and nonpregnant states

Toshinari Minamoto, M.D., Katsuhiko Arai, D.V.M., Shun Hirakawa, M.D., and Yutaka Nagai, Ph.D.

Tokyo, Japan

The distribution of collagen types in pregnant and nonpregnant uterine cervices was examined by immunoperoxidase staining with the use of type-specific anticollagen antibodies. The nonpregnant cervix, composed of dense fibrous tissues, was diffusely stained with antibodies to type I and type III collagens. Type IV collagen was located only in the basement membrane region. In the cervix at term pregnancy, a marked decrease in fibrous connective tissue with increased proportions of smooth muscle fibers was characteristic, forming expanded spaces in between due to edema (clear spaces) with focal infiltrations of polymorphonuclear leukocytes. Type I and type III collagens were distributed only around smooth muscle fiber bundles with some fibroblasts attached. Type IV collagen was distributed in a linear fashion delineating individual smooth muscle fibers and vascular basement membranes. A possible role of infiltrated polymorphonuclear leukocytes in the dissociation of fibrous connective tissues of the cervix at term pregnancy is discussed. (Am J Obstet Gynecol 1987;156:138-44.)

Key words: Anticollagen antibody, collagen, immunohistochemistry, cervix in pregnancy

In contrast to the myometrium of the corpus, the uterine cervix in the nonpregnant woman is predominantly composed of dense connective tissue, the principal component of which is dense and tightly packed collagen fibers.[1] Smooth muscle fibers account for 10% to 15% of the normal cervical substance and are scattered sparsely and at random throughout the tissue. Histologic and biochemical studies confirmed these findings and showed that the content of smooth muscle fibers decreased from the upper cervix downward.[2]

During the period of term pregnancy to labor, the cervix reveals dramatic changes such as softening and ripening. The characteristics of the cervix are to permit it to carry out its vital but conflicting functions of acting as a barrier to retain the conceptus and opening at an appropriate time to permit the conceptus to be expelled from the uterus. Morphologic changes in softening and ripening of the cervix are characterized by dissociation and branching of collagen fibers into their fibrillar components and expansion of the interfibrillar spaces (clear spaces) due to edema.[1-3] Biochemical studies showed that the concentration of collagen in the cervix at term pregnancy was decreased, while glycosaminoglycans, especially hyaluronic acid, and water contents were increased.[4]

Nonpregnant					
1-9	38-49 (mean 45)				Hysterectomy for leiomyoma in all cases
Pregnant					
10	46	8 wk, 2 days			Hysterectomy for leiomyoma
11	39	9 wk			Hysterectomy for leiomyoma
12	25	38 wk, 6 days	1	30	Cephalopelvic disproportion, breech
13	38	39 wk, 1 day	0.5	10	Repeat cephalopelvic disproportion, breech
14	41	39 wk, 3 days	0.5	20	High-risk pregnancy
15	34	39 wk, 3 days			Hysterectomy for atony of uterus after spontaneous labor
16	32	39 wk, 6 days	0	10	Repeat cephalopelvic disproportion, fetal distress
17	30	40 wk	2	20	Cephalopelvic disproportion
18	26	42 wk, 3 days	5	50	Fetal distress

Our previous studies showed that the solubility of collagen, particularly type I collagen, in the cervix was significantly increased at term pregnancy.[5] In parallel, the activities of collagen-degrading enzymes such as collagenase and collagenolytic peptidase were also elevated with softening and ripening of the cervix.[6] Although the distribution and function of collagen types in various tissues have recently been elucidated,[7] little information is available as to those in the ripening process of the pregnant cervix at present.

Therefore we studied distributions of collagen types I, III, and IV in nonpregnant and pregnant cervical connective tissues by the immunoperoxidase staining method with type-specific anticollagen antibodies used to elucidate how collagen types are involved in dilatation and effacement of the cervix in term pregnancy.

Material and methods

Uterine cervical tissues from 18 women of child-bearing age were examined. Cervical tissues from nonpregnant women were obtained at the time of hysterectomy for leiomyomas, and uninvolved regions were used. Cervical tissues were also obtained from pregnant women at term at the time of cesarean section and from patients of 8 and 9 weeks' gestation with leiomyomas (Table I). These cervical tissues were fixed with 10% buffered formalin and embedded in paraffin for histochemical and immunoperoxidase staining.

Type-specific rabbit antibodies to type I collagen (from fetal calf skin) and rat antibodies to type III and type IV collagens (both from the human placenta) were purified by affinity chromatography.[8] Antibodies to types I, III, and IV collagens were shown to have reciprocal titers of 2^{11}, 2^{10}, and 2^{12}, respectively, by passive hemagglutination assays and showed no cross-reaction with other types of collagens.

Paraffin sections were routinely stained with hematoxylin and eosin, azan, and phosphotungstic acid–hematoxylin.

Immunoperoxidase staining was performed according to the method described by Sternberger et al.[9] Paraffin sections were pretreated with 0.01% protease (type VII, Sigma Chemical Co., St. Louis, Missouri) in Tris hydrochloride buffer, 0.05 mol/L, pH 7.6, at 37° C for 10 minutes and then incubated with antibodies to type I, type III, or type IV collagen, diluted to 1:10, 1:20, and 1:20, respectively with phosphate-buffered saline, 0.01 mol/L, pH 7.2. Swine immunoglobulin G to rabbit immunoglobulin G with rabbit peroxidase-antiperoxidase complex (Dakopatts, Glostrup, Denmark) and rabbit immunoglobulin G to rat immunoglobulin G (Cappel Laboratories, Cochranville, Pennsylvania) with rat peroxidase-antiperoxidase complex (Jackson Immuno-Research Laboratories, Inc., Avondale, Pennsylvania) were used in a dilution of 1:100 with phosphate-buffered saline. As a control, nonimmunized rabbit and rat immunoglobulin G was used instead of type-specific anticollagen antibodies.

Results

In the nonpregnant uterus, the cervix was mainly composed of dense fibrous connective tissues, among which some smooth muscle fibers were scattered sparsely. These two major fibrous components were intermingled with no particular alignment and were tightly packed with each other. Immunoperoxidase staining revealed that type I and type III collagens were diffusely distributed in the dense fibrous connective tissues with no remarkable differences shown in the distribution of these collagens (Fig. 1, *a* and *b*). Type IV collagen was observed in a fine linear fashion

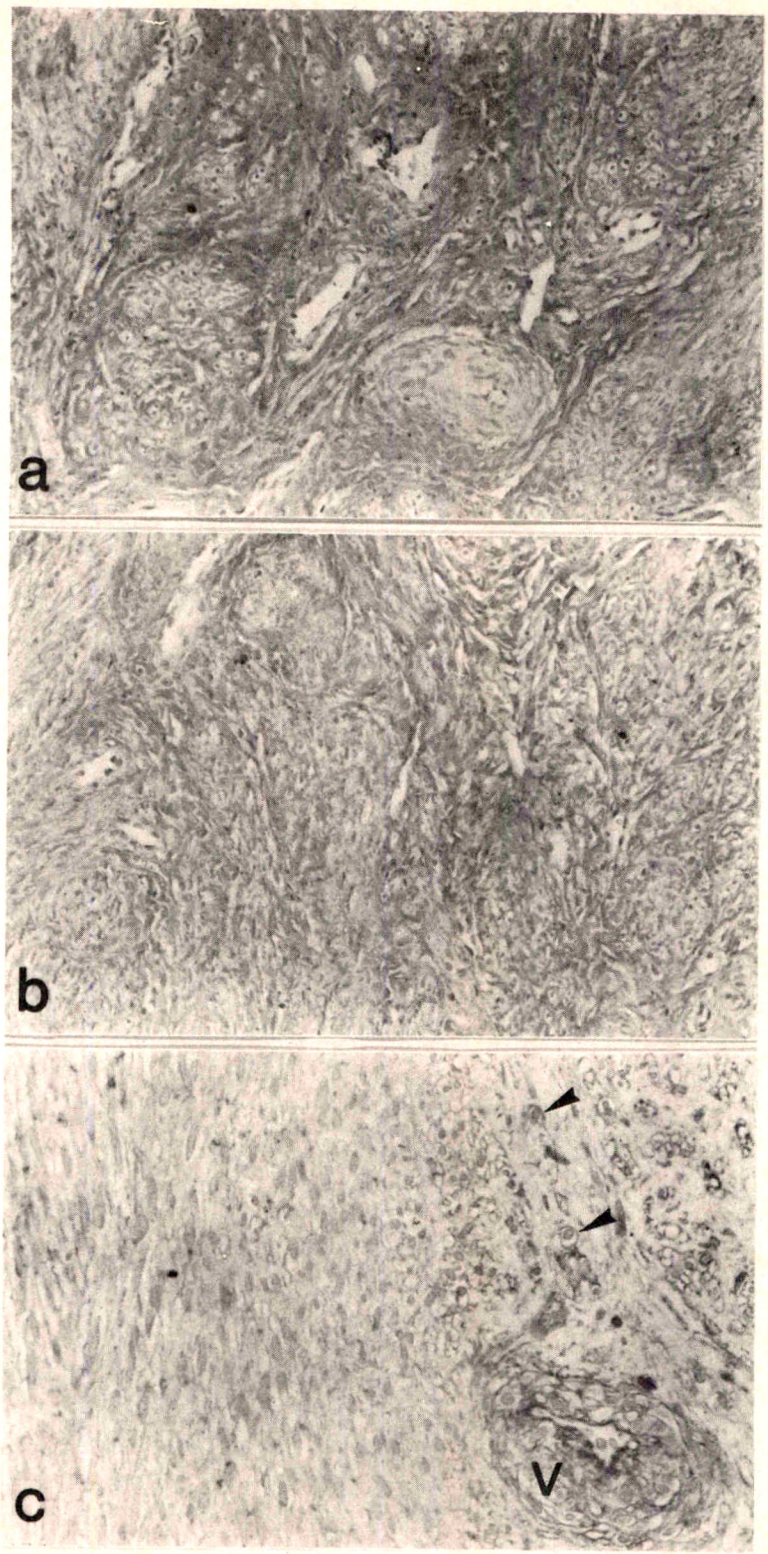

Fig. 1. Immunoperoxidase staining for type I, type III, and type IV collagen in the nonpregnant cervix. Type I *(a)* and type III *(b)* collagen was distributed diffusely in the dense fibrous tissue, while type IV collagen *(c)* delineated basement membranes. *V*, Blood vessel; *arrowheads*, immunoreactive components delineating smooth muscle fibers. (Original magnification ×200.)

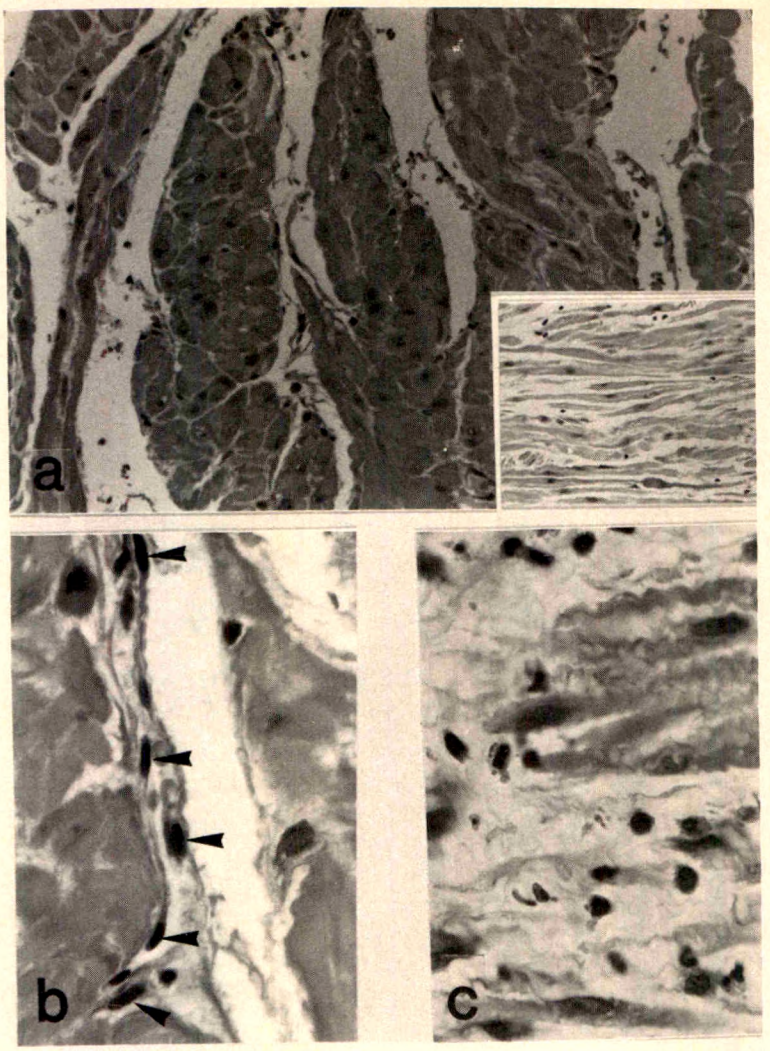

Fig. 2. The cervix of term pregnancy showing an increased proportion of smooth muscle fibers aligned in a particular direction and clear spaces in between *(a)*. Some smooth muscle fibers were locally dissociated (see *inset*) in the area where polymorphonuclear leukocytes were infiltrated (see also *c*). Some fibroblasts *(arrowheads)* were observed along with thin collagenous fibers around the smooth muscle fibers *(b)*. Polymorphonuclear leukocytes were focally infiltrated in the clear space *(c)*. (*a*, Including *inset*: Hematoxylin and eosin. Original magnification ×200. *b* and *c*: Hematoxylin and eosin. Original magnification ×400.)

at the blood vessels and along individual smooth muscle fibers showing the delineation of the basement membrane but was not distributed in the dense fibrous connective tissue (Fig. 1, *c*). Nonimmunized rabbit and rat immunoglobulin G showed no reaction with the tissue specimens examined (data not shown).

In term pregnancy, dissociated and hypertrophic smooth muscle fibers were aligned in particular directions (Fig. 2, *a*), and some smooth muscle fibers were locally dissociated (Fig. 2, *a*, *inset*) in the area where polymorphonuclear leukocytes were infiltrated (see also Fig. 2, *c*). The content of fibrous connective tissue components was markedly decreased and the remaining thin fibrous components were attached around smooth muscle fibers and bundles, where some fibroblasts were present (Fig. 2, *b*). The spaces between smooth muscle bundles or collagen fibers were expanded because of edema (clear space), and infiltrated polymorphonuclear leukocytes were focally observed in the clear space (Fig. 2, *c*). Immunoperoxidase staining with the use of anticollagen antibodies showed quite similar distributions of type I and type III collagen around smooth muscle bundles (Fig. 3, *a* and *b*), although type III collagen was also distributed within the bundles (Fig. 3, *b*). Type IV collagen delineated individual smooth muscle fibers and basement membranes

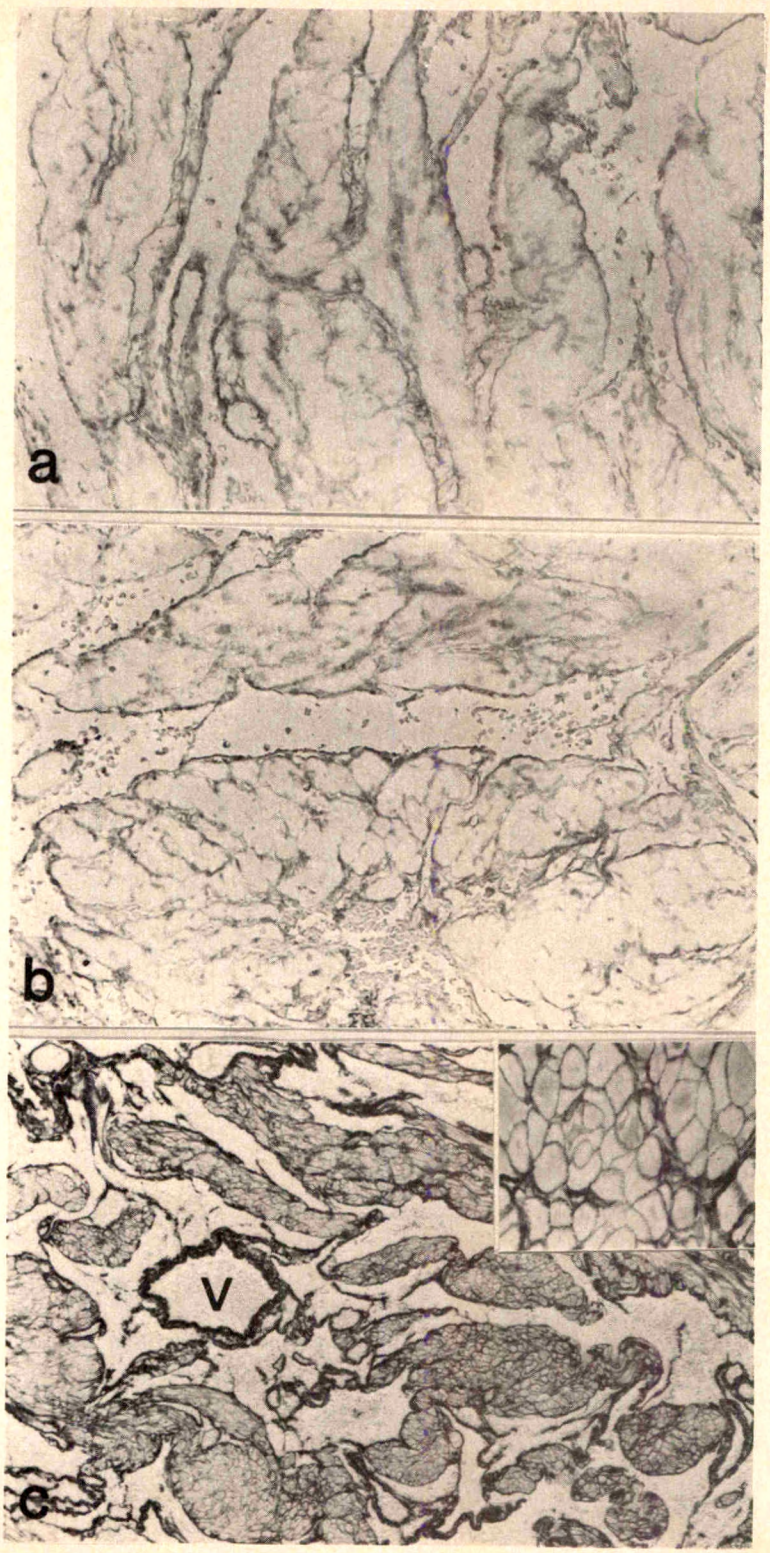

Fig. 3. Immunoperoxidase staining for type I *(a)* type III *(b)*, and type IV *(c)* collagen in the term pregnant cervix. The *inset* of *c* shows individual smooth muscle fibers outlined by type IV collagen. *V*, Blood vessel. (*a* and *b*: Original magnification ×200. *c*: Original magnification ×100, *Inset* of *c*: Original magnification ×250.)

of blood vessels (Fig. 3, *c*). The clear spaces and smooth muscle fiber itself did not react with any antibodies used, and nonimmunized rabbit and rat immunoglobulin G showed no reaction with the tissue specimens examined (data not shown).

In the cervical tissues of early gestation (8 and 9 weeks) compared with the nonpregnant cervix, little change was obsesrved in smooth muscle fibers although fibrous connective tissue regions became slightly sparse in pregnancy. The distribution of collagen types I, III, and IV resembled that of the nonpregnant cervix.

Comment

The uterine cervix plays active roles, namely, dilatation and effacement, during pregnancy and labor. Dilatation and effacement are not simply a result of mechanical forces but also depend on a ripening process involved in the cervix. The main process of ripening occurs in the last 3 to 4 weeks of pregnancy.[10] Ripening disorders may cause serious obstetric complications; that is, extensive ripening before term pregnancy may produce cervical incompetency, whereas delayed ripening or a rigid cervix at term may lead to prolonged labor or postterm delivery. For the resolution and prevention of these problems, elucidation of detailed mechanisms of the normal ripening process is indispensable.

Histologic examination of the cervix in term pregnancy showed that the cervical tissue became very loose, because of the decrease in and dissociation of collagen fibers and expansion of the clear space caused by edema. These observations agree with the findings previously described.[1, 3] The proportion of smooth muscle fibers that became hypertrophic increased in term pregnancy. A relatively higher population of smooth muscle fibers in our cases compared with those of previous reports[3] can be explained by the location of the specimens examined, that is, from the lower uterine segment adjacent to the obstetric internal os where cesarean section is generally performed. It is of interest that these smooth muscle fibers were aligned in particular directions (Fig. 2, *a*), which was in marked contrast to the fibers in the corresponding region, or between the anatomic and histologic internal ora, of the nonpregnant cervix (Fig. 1). The smooth muscle bundles likely play a role in the maintenance of the conceptus until delivery and prepare to extend in appropriate directions at delivery to prevent cervical laceration.

In the pregnant cervices examined, dense fibrous connective tissues were markedly dissociated, and thin collagen fibers were located exclusively around smooth muscle bundles with some fibroblasts. Biochemical analysis has indicated decreased concentration[4] and increased solubility[5] of collagen, especially type I collagen, at term pregnancy. The activities of collagen-degrading enzymes, including collagenolytic peptidase, were also elevated with ripening of the cervix.[6] Infiltration of polymorphonuclear leukocytes into the clear space seems to be closely related to collagenolysis,[3, 11-14] since our recent studies on the role of inflammatory cells in tissue (stroma) reactions have shown that, during infiltration of polymorphonuclear leukocytes from the bloodstream to the tissues, the inflammatory cells acquire a factor that stimulates connective tissue cells, including fibroblasts, to produce collagenase[11] and prostaglandin E_2[12] and to suppress collagen synthesis.[13] This sort of stromal reaction may also occur in the pregnant cervix in association with the collagen-degrading enzyme system directly derived from polymorphonuclear leukocytes,[3, 14] since recent studies have shown that intracervical application of prostaglandin E_2 induces the ripening process in the pregnant cervix.[15]

The functional characteristics of interstitial collagen are to provide tensile strength that is essential to hold tissues together as functional units, as well as to permit tissues to be pliable and/or extensible, and those of basement membrane (type IV) collagen are to serve as a stable backbone or supporting meshwork, as mechanical and ionic filters, and as a substratum for cell support and separation.[7] The distribution of collagen types I, III, and V and fibronectin in the corpus myometrium in normal and hypertensive pregnant patients was reported recently, with a description of the correlation between disruption of the uterine structure and the amount of urinary proteins excreted.[16] Another important observation is that prolonged dilatation time is closely related to increased concentrations of collagen in the lower part of the cervix.[4]

Immunohistochemical staining with the use of type-specific anticollagen antibodies revealed that type I and type III (interstitial) collagens were codistributed around smooth muscle bundles, but not in wide clear spaces, and that type IV (basement membrane) collagen delineated each smooth muscle fiber as well as the vascular basement membranes.

On the basis of these views, the distribution of collagen types in term pregnancy should serve the dual but conflicting functions of acting as a barrier to retain the conceptus and opening the cervix at the time of delivery. Further histologic and biochemical investigations on the ripening process in the pregnant cervix are currently in progress in our laboratory.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

The planning of pregnancy among low-income women in central Harlem

Marie C. McCormick, M.D., Sc.D, J. Brooks-Gunn, Ph.D., Thomasine Shorter, M.S.W., Claudina Y. Wallace, M.D., M.P.H., John H. Holmes, B.S., and Margaret C. Heagarty, M.D.

Philadelphia, Pennsylvania, Princeton, New Jersey, and New York, New York

A planned pregnancy is considered desirable, in part because of the potential of a better pregnancy outcome. Since the improvement of pregnancy outcome is of particular relevance in low-income populations, we have compared the characteristics of women with planned and unplanned pregnancies in central Harlem with regard to those factors that might affect pregnancy planning such as sociodemographic factors, attitudes toward child-rearing, environmental stress, social support, and maternal mental health. Of the 416 women in the study, a minority (27%) reported their pregnancy as being planned. They differed from the remainder in being more likely to be married and/or living with a boyfriend or husband and to have been born outside New York City. The two groups did not differ in any other risk factor or in outcome in terms of birth weight and gestational age. The results provide little support for the lack of planning of pregnancy as an indicator of risk in a low-income population and suggest that improvement of perinatal outcome must involve more broadly based interventions that are not confined to the periconceptional period. (Am J Obstet Gynecol 1987;156:145-9.)

Key words: Planned pregnancy, low-income women, obstetric risk factors

A planned pregnancy is considered desirable for many reasons, and this desirability is reinforced by the observation of a statistical association between such pregnancies and better obstetric and perinatal outcomes.[1] However, the way in which planning for pregnancy may relate to pregnancy outcome remains to be established. One mechanism is the potential for prepregnancy screening for obstetric risk, although this relationship has received little empiric examination. Alternatively, women unable to plan their pregnancies may present higher obstetric risks for other reasons,[2, 3] for example, adolescent childbearing or reproductive problems that preclude effective contraception. Another factor may be increased ambivalence and anxiety in women with unintended or unwanted pregnancy, which may be associated with an increased risk for a variety of obstetric complications.[4, 5] Finally, absence of planning for pregnancy and increased obstetric risk may reflect other characteristics of the woman's environment which may affect pregnancy outcome such as physical and psychological stress and inadequate social support.[6-8]

The issue of pregnancy planning seems especially important to low-income populations in which lack of planning and perinatal morbidity are more common. Unfortunately, except for studies of low-income adolescent mothers, the factors associated with pregnancy planning in these populations have not been described. This paper describes the correlates of planning among a group of urban, low-income pregnant women.

Material and methods

Sample. The data for this study were collected as part of an evaluation of a program designed to provide enriched prenatal services in an urban low-income community, central Harlem. The sample consists of 599 women: 435 who enrolled for prenatal care at one of the four satellite clinics affiliated with Harlem Hospital and a sample of 164 women registering for prenatal care at the prenatal clinic within the Harlem Hospital Center during the period August 1982 and September 30, 1983. The sample represents 78% of all women eligible for the study. The remainder were eliminated as a result of spontaneous or elective abortions or because they did not continue care within the Harlem Hospital System.

Data collection. Each woman was asked to complete a self-administered questionnaire, generally during her

*p-Value for χ^2 with appropriate degrees of freedom ($p < 0.05$).

first or second prenatal visit. Completed questionnaires were obtained from 76.5% (458) of the entire sample. Based on data abstracted from the obstetric record, it was found that those women who did not complete the questionnaire were more likely to be older, married, or classified as Hispanic or to have been born outside the United States. Respondents and nonrespondents did not differ with regard to the presence of historic or existing obstetric risk factors or the timing of their entry into prenatal care.

The research questionnaire consisted of questions in the following four areas:

1. Sociodemographic characteristics of the patients, which consisted of questions to ascertain age, educational level, birth place, duration of residence in New York City, marital status, membership in the maternal household, and family income.

2. Maternal attitudes toward the new child as determined by three questions concerning the mother's own assessment of her confidence about caring for the new child, her choice of names for the infant, and her previous child-rearing experiences. Included in these questions was a question as to whether the pregnancy was planned and a question as to whether the woman was surprised at being pregnant.

3. Maternal health behavior which involved questions about maternal smoking[9, 10] and drinking behavior derived from standard questionnaires.

4. Maternal exposure to stressful events, social support, and mental health. The first was assessed with use of a modification of the Dohrenwend's PERI scale,[11] which ascertained the presence of 17 stressful events in the year before the start of antenatal care. Maternal social support was ascertained by asking the women what they would do in each of six hypothetical situations: two in which they needed to borrow a modest amount of food or money, two in which they required assistance during an illness of varying durations, and two in which they needed advice or emotional support. The items were scored to indicate the number of situations in which the women could name an individual (by name and relationship to them) to whom they felt they could turn for help.[12] Mental health status was estimated by the 22-item version of the General Health Questionnaire,[13] which assesses general well-being, depression, anxiety, and somatic complaints. Scores above 5, with use of the dichotomous scoring system, have been shown to indicate clinically important mental distress.

In addition to the above items, previous reproductive history, birth weight, and gestational age were abstracted from the medical record.

All methods were reviewed and approved annually by the Institutional Review Board of the University of Pennsylvania. Differences in the distribution of categorical variables between those with planned pregnancies and those without were tested with use of χ^2, with Yates correction. All analyses were done with use of the Biomedical Data Package.[14]

Results

Of the 458 women who completed the questionnaire, 416 (91%) answered the question, "Did you plan this pregnancy?"; most of these women (303, or 73%) described their pregnancy as unplanned. Reinforcing the notion that most pregnancies were unplanned was the fact that most of those with unplanned pregnancies (198, or 65%) also reported themselves as surprised by the pregnancy.

Sociodemographic characteristics. As seen in Table I, many (46%) of these women had not completed high school and most (71%) were single. A smaller but substantial proportion (22%) were adolescent. Most were born in New York City. Married women and those born outside New York City were statistically more likely to report a planned pregnancy. The differences in maternal ages between those with planned and those with unplanned pregnancies approached a level of statistical significance ($p = 0.06$), with younger women being somewhat more likely to report their pregnancy as unplanned.

Maternal attitudes toward the infant. Although for the majority (58%) of women this pregnancy represented the birth of their first child, most (86%) expressed confidence in their child-caring ability; 53% had already selected a name for the anticipated infant.

Table II. Health behavior patterns of central Harlem women with planned (n = 113) and unplanned (n = 303) pregnancies

Behavior pattern	*Planned (%)*	*Unplanned (%)*	*Total (%)*
Cigarette smoking			
Never	44.6	42.6	43.2
Before pregnancy/not now	15.2	15.8	15.6
Less than before pregnancy	23.2	26.2	25.4
Same or more	17.0	15.4	15.9
Alcohol use			
Never	39.6	39.7	39.7
Before pregnancy	56.6	49.2	51.1
Now	3.8	11.2	9.2
Trimester of start of prenatal care			
First	43.2	36.2	38.0
Second	48.6	48.4	48.5
Third	8.1	15.4	13.6

None of these variables discriminated between those who planned and those who did not plan the pregnancy. However, those with planned pregnancies were marginally more likely to express confidence about their child-caring ability (91% versus 84%, $\chi^2 = 2.89$, $p = 0.09$).

Maternal health behaviors. More than half (57%) of these women reported that they smoked, but 25% reported that they were smoking less; 16% reported that they had stopped smoking completely during their pregnancy (Table II). Although most women reported alcohol use, few (9%) reported continued use during the pregnancy. Most (62%) enrolled in prenatal care after the first trimester of pregnancy.

Neither the use of tobacco or alcohol nor the timing into prenatal care discriminated between those who did and those who did not plan their pregnancies. Women who planned were marginally more likely to stop drinking during pregnancy than those who did not.

Maternal stress, social support, and mental health. Most women (71%) had experienced at least one major stressful event (excluding pregnancy) in the year before conception (Table III). Moreover, these mothers' levels of social support were low; few (29%) lived with a husband or boyfriend, and the majority (56%) were unable to name anyone who could help them in four or more of the presented hypothetical situations. In view of these findings, it is not surprising that a substantial proportion of these women (30%) scored in the distressed range of the General Health Questionnaire. Women who reported living with a husband or boyfriend were statistically more likely to have planned their pregnancies.

Previous reproductive history and pregnancy outcome. Among these women, almost 10% had had a previous low birth weight infant, and 14% had experienced at least one spontaneous abortion, with 22% having had an elective abortion (Table IV). None of these factors were associated with the planning of pregnancy. Of the 361 with obstetric outcome data (87% of those who delivered at Harlem Hospital), 10% weighed <2500 gm and 15% were preterm (<38 weeks' gestation). The outcome of pregnancy in terms of the infant's gestational age or birth weight did not differ with the presence or absence of maternal pregnancy planning.

Table III. Stressful events, social support, and mental health among central Harlem women with planned (n = 113) and unplanned (n = 303) pregnancies

Comment

Variations in terminology make cross-study comparisons of intendedness of pregnancy difficult. The available national data[2] are developed from questions about whether the pregnancy is "wanted" and whether it is

wanted at the time of its occurrence. With use of these questions, the percentage of "unwanted" pregnancy is declining and is currently at a level of about 10%. However, of those pregnancies defined as wanted, more than one quarter (28%) are defined by the respondents as mistimed. Thus more than a third of women consider their pregnancies unintended at the time of conception. In populations similar to the present study (low income, urban, never married), the proportions of unwanted or mistimed pregnancies are substantially higher: 30% unwanted and 41% mistimed, which suggests that as many as 59% of pregnancies in these women are not intended.

In this study the percentage of "unplanned" pregnancies is somewhat higher (73%). However, we deliberately inquired about planning rather than wanting because of a concern that social desirability might lead to underreporting of unwantedness during an interview. Thus women who do not plan but want the pregnancy when it occurs may be one source of discrepancy and may reflect an underestimate of the wantedness of pregnancy in urban low-income populations. On the other hand, the national data, may overestimate wantedness, because the number of women who report a pregnancy as wanted increases with time as those who did not intend to become pregnant begin to accept and anticipate the birth of a child. Regardless of the precision of either data set, these data indicate that despite the availability of effective contraception, substantial numbers of pregnancies of urban low-income women in this country are unplanned at their conception.

Although the high proportion of unintended pregnancies was not unexpected, the failure of many of the usual socioeconomic and life-style variables to discriminate among the groups who planned and those who did not plan their pregnancies was not expected. These data suggest that urban low-income women who plan their pregnancies are somewhat more likely to be older, to live with a husband or boyfriend, to have been born outside the city of their current residence, and to be more confident about their ability to cope with the new baby. In addition, the concept of "covert" pregnancy planning is not supported by this study; no differences were found among the women who did not plan but were not surprised by the fact of pregnancy and those who did not plan but did report surprise by the event.

These results do not support the conventional image of the urban low-income mother with an unintended or unplanned pregnancy as one whose high levels of stress and lack of a social support system or mental distress hamper her ability to use reliable contraceptive methods. However, women who planned their pregnancy are significantly more likely to have the social stability involved in a relationship with a man, at least to the extent of living with a husband or boyfriend. These data support the findings of other investigations of low-income women and their decisions about abortion or continuation of pregnancy that the characteristics of the woman's relationship with her male partner are the most predictive factor of a decision to continue her pregnancy.[15] Both this study and previous work argue for the proposition that reproductive decisions of low-income women are made in the context of their specific situations and relationships and cannot be predicted by relatively static characteristics of the woman.

The absence of significant differences in obstetric outcome among women who did and those who did not plan their pregnancies reflects similarities in the presence of factors known to influence pregnancy outcome (tobacco use, timing of prenatal care, etc.). This lack of difference between those with planned and unplanned pregnancies indicates a missed opportunity, since even those with planned pregnancies are not able or encouraged to initiate their prenatal care early or to alter behaviors known to affect obstetric outcome adversely.

Our results differ from some investigations that have noted an association between unwanted pregnancy and poor obstetric outcome.[16] The discrepancy between these findings and the present study may reflect differences in the populations studied and in the influence of social class, or more specifically poverty, as mediators of the effects.

The limitations of these results must be noted. First, the study population consists of low-income women who seek care from clinics affiliated with a public general hospital; it does not include those who seek care outside this system or those who receive no prenatal care before delivery. Second, not all eligible women completed the baseline questionnaire. While comparisons of respondents with nonrespondents revealed no differences in incidence of prenatal problems or obstetric outcome, nonrespondents tended to be older, to be categorized as Hispanic, and to enroll in the earlier stages of the program. These differences can in part be explained by early logistic problems in program implementation and an initial lack of a Spanish version of the questionnaire.

Despite these limitations, these findings have important implications for the development of programs of reproductive services for urban low-income populations. If high levels of unplanned or unintended pregnancies are continuing among urban low-income women and if no obvious maternal characteristics permit discrimination between those who will from those who will not plan, two separate strategies for intervention seem necessary.

First, preconceptional care programs as recommended by the recent Institute of Medicine report[1] must involve approaches that do not require previous

knowledge of the timing of pregnancy and must be directed to the entire population of urban low-income women. In view of the apparent situational nature of the reproductive decisions of these women, multiple strategies for counseling low-income women about the adverse risks of pregnancy must be undertaken. The entire health and educational system with responsibility for these women, not just the obstetric and family planning community, must become involved in a systematic and consistent pattern of counseling about adverse health behaviors, smoking, need for prenatal care, contraceptive use, and the need for appropriate spacing of pregnancies. Considerable efforts must be directed toward training other health professionals, such as pediatricians and general physicians, in these matters so important to the health status of low-income pregnant women and their children.

Second, these results reinforce the importance of aggressive management of medical problems and adverse health behaviors as early in pregnancy as possible. This study presents a picture of a group of women, regardless of whether they have planned their pregnancies, who are under high levels of environmental stress and emotional distress and many of whom continue to smoke or to use excessive alcohol. Although traditional medical services have done much to improve the morbidity of pregnancy, these services can be anticipated to make no more than a marginal contribution to the health status of this group of pregnant women. Additional supportive services specifically designed to address these problems must be added to prenatal care services if additional improvement is to be expected.

We wish to acknowledge the insights and critical contributions of Vanessa Smith, Anna Soto, Brenda Williams, Sonya Branch, Agnes Cunningham, Arnecia Morgan, and Barbara Price and the helpful comments from consultants and staff of the Commonwealth Fund, as well as the assistance of Dr. David Cornfeld and Merceda Lafferty in preparation of the manuscript.

Ultrasonically evident fetal nuchal skin thickening: Is it specific for Down syndrome?

Ants Toi, M.D., Gary F. Simpson, M.D.,* and Roy A. Filly, M.D.

Hamilton, Ontario, Canada, and San Francisco, California

Fetal nuchal thickening in the second trimester is suggested as an ultrasonographic sign strongly suggesting the presence of Down syndrome. To better understand this potentially valuable observation, we explored aspects of the finding not considered in previous reports. The published data were reanalyzed to estimate statistically the presence of the sign in a low-risk obstetric population. Second, films of chromosomally normal fetuses were reviewed to confirm the normal range of measurement. Finally, autopsy reports of aborted Down syndrome fetuses were reviewed. Our results confirm that true nuchal thickening is present in some second-trimester Down syndrome fetuses. Unfortunately, a positive sign occurs in a significant proportion of chromosomally normal fetuses. Also our calculations predict a high incidence of false positive results in a low-risk obstetric population. Consequently we urge caution in the interpretation of these findings until prospective characterization of these observations is available. (Am J Obstet Gynecol 1987;156:150-3.)

Key words: Down syndrome, ultrasonics, fetus

Down syndrome has been diagnosed by pediatricians for many years by its phenotypical external features.[1,2] Previous authors emphasize that multiple characteristics need to be present before a confident diagnosis can be suggested. They also stated that any of the multiple findings in Down syndrome infants may be found in chromosomally normal children.

Recently two reports described an ultrasonographically visible sign that was highly specific for predicting the presence of Down syndrome in the second trimester of pregnancy. The sign is an abnormal skin thickness of greater than 5 mm behind the neck.[3,4] In the reported combined patient series this finding was present in four of 11 (36%) Down syndrome fetuses and in only one chromosomally normal fetus. The authors further suggested that if the sign is present, then "it appears to be highly specific and should lead to counseling the parents regarding its implications and their options." The serious clinical implications of these suggestions prompted us to analyze our own material to better understand this potentially valuable ultrasonographic observation.

Table I. Calculated changes in test performance as incidence of Down syndrome changes in the population

	Test population	*All pregnancies*	*Pregnancies in women under age 30*
Incidence	1:155	1:660	1:1500
Sensitivity (%)	36.4	36.4	36.4
Specificity (%)	99.9	99.9	99.9
Positive predictive value (%)	80.0	48.3	19.6
Negative predictive value (%)	99.6	99.9	99.9

With the standard 2 × 2 table, if we know the incidence, sensitivity, specificity, we can calculate the new contents of each cell as the incidence changes. This then allows us to estimate the new positive and negative predictive values in test populations that have differing incidences of disease.[6]

Methods

We studied the following questions: (1) What would be the expected performance of this test in the general obstetric population that is at low risk for Down syndrome? (2) Is this sign visible in chromosomally normal fetuses? (3) How frequently is nuchal thickening evident in Down syndrome fetuses aborted in the second trimester?

Test performance in low-risk population. The published data were analyzed with a standard 2 × 2 decision matrix that helps to determine the usefulness of a diagnostic test.[5] These results were then used to estimate the expected performance of this test in the normal low-risk obstetric population.

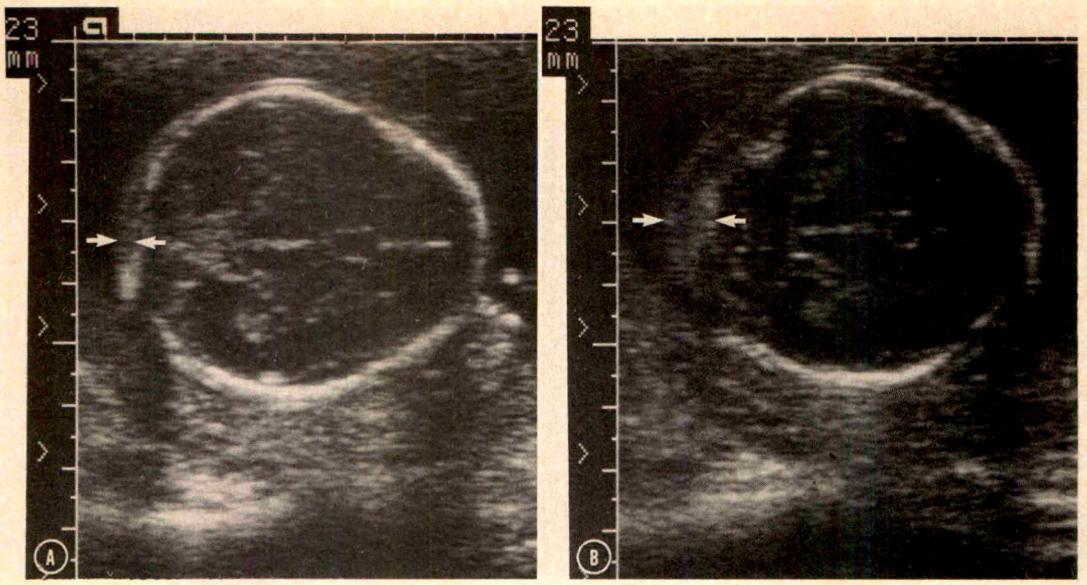

Fig. 1. *A*, Ultrasonogram of normal fetal head at 21 weeks' gestation showing normal skin thickness *(arrows)* behind the occiput. Here the plane of section is not steeply angled to the baseline. It is cephalad to the cerebellum and includes the occipital lobes and ambient cistern. *B*, Ultrasonogram of same fetus showing nuchal thickening of 8 mm measured as indicated by the *arrows*. Note that the plane of section in this image is more steeply angled to the baseline since the cerebellum and cisterna magna are included in the section.

Is the sign visible in chromosomally normal fetuses? We reviewed the ultrasonograms of 28 pregnancies undergoing detailed ultrasonic assessment for elevated amniotic fluid α-fetoprotein levels. This group was selected since all of these fetuses had been proved to be chromosomally normal and were in the same gestational age range as those of the previous studies. The gestational ages ranged from 18.5 to 25.5 menstrual weeks. Nuchal tissue thickness was measured on transaxial images of the fetal head that were suitable for biparietal diameter measurement. The planes of section included the thalamus, third ventricle, and occipital tissues. The distance from the external surface of the occipital bone to the external surface of the skin was measured. If the scan angle was such that the posterior part of the plane of section was caudal to the ossified part of the occipital bone, then the thickness of tissue between the cisterna magna and the external surface of the skin was taken. In each instance, the maximal value was recorded.

In an additional seven fetuses with normal chromosomes verified by amniocentesis, we deliberately set out to see if we could create a picture showing nuchal thickening by varying the angle of the plane of section while maintaining a transaxial orientation that always included the third ventricle and thalamus.

How often does nuchal thickening occur in Down syndrome fetuses in the second trimester? The autopsy reports of fetuses aborted with amniocentesis-verified Down syndrome at the University of California, San Francisco, were reviewed with attention to external soft tissue changes, especially in the region of the neck. Thirteen reports were available. Menstrual age ranged from 18 to 23 weeks. Since no anthropomorphic measurement criterion is available for nuchal skin thickness, we relied on the experience of the examining pathologist to visually differentiate thickened from normal neck tissues.

Results

Test performance in the low-risk population. In the combined published reports, 1704 patients at 15 to 20 weeks' gestation were assessed for nuchal thickening at the time of genetic amniocentesis. Eleven fetuses had Down syndrome, for an incidence of 11/1704, or one case per 155 patients. The positive finding of isolated nuchal thickening was present in four and absent in seven Down syndrome fetuses. One of the seven, however, had a cardiac anomaly and hydrops, a combination that also suggests Down syndrome. In only one instance was the finding present in a chromosomally normal fetus.

This allows the following calculations: incidence = 11/1704 (1:155); sensitivity = 4/11 (36%); specificity = 1692/1693 (99.9%); positive predictive value = 4/5 (80%); negative predictive value = 1692/1699 (99.6%).

This test population had an unusually high incidence

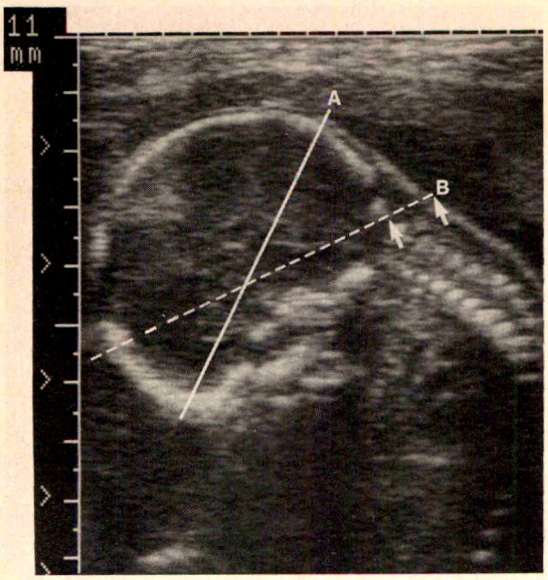

Fig. 2. Dorsal midsagittal ultrasonogram of a chromosomally normal fetus showing the normal nuchal soft tissues. A transverse head image obtained along plane *A* would give an image as in Fig. 1, *A*, with "thin" occipital tissues. However, a steeply angled image along plane *B* would appear as in Fig. 1, *B*, and show spurious thickening of nuchal tissues *(arrows)* as a sectioning artifact. The transverse ultrasonogram along plane *B* would show the lower cerebellum and cisterna magna.

of Down syndrome (1:155). Under these conditions a positive test indicates that four of five (80%) fetuses will have Down syndrome.

If we know the incidence of the disease in another population, for instance, the normal low-risk obstetric population, then we can estimate the expected performance of the test in that instance.[6] The published incidence of Down syndrome in mothers between 15 and 29 years of age is 1:1500.[7]

The calculations give the following results (Table I): sensitivity = 36%; specificity = 99.9%; positive predictive value = 20%; negative predictive value = 99.9%.

Note that the sensitivity and specificity have not changed but the clinically important positive predictive value has decreased to 20%.

Is the sign visible in chromosomally normal fetuses? In our study, nuchal thickening beyond 5 mm was present in six of 28 (21%) chromosomally normal fetuses examined for increased α-fetoprotein values in the amniotic fluid and ranged from 6 to 12 mm. None of these fetuses had hydrops, generalized skin thickening, or fluid collections in serous cavities. Only one had an anomaly, that being a mild dilation of cerebral ventricles without any other detectable abnormality. This anomalous fetus did not have evident nuchal thickening. When nuchal thickening was found, it was always present on a section taken for biparietal diameter measurement, which included the thalamus and lower cerebellum and cisterna magna.

In the group of seven chromosomally normal fetuses in whom we deliberately set out to see if we could create a falsely thickened neck, we found that as the image plane became more steeply angled caudally and intersected lower levels of the cerebellum and occiput, we were always able to show skin thickness >5 mm (Figs. 1, *A* and *B*, and 2).

How often does nuchal thickening occur in Down syndrome fetuses in the second trimester? There were 13 autopsy reports available. The neck was specifically stated to be normal in six abortuses. An additional three abortuses were noted to be externally normal, but the neck was not specifically mentioned. A further fetus had severe nonimmune hydrops. Another was macerated after spontaneous death in utero. Neck thickening was evident in two fetuses. This gives an incidence of two fetuses with isolated nuchal thickening in a total of 11 (18%) if the hydropic and macerated fetuses are excluded.

Unfortunately we cannot comment on the ultrasonographic frequency of occurrence of nuchal thickening at the University of California, San Francisco, Hospital since patients undergoing amniocentesis because of late maternal age have only a limited-guidance scan without detailed fetal assessment. Images were available for only a few patients in whom a major finding, such as severe hydrops, was evident at the time of amniocentesis.

Comment

Most Down syndrome infants are born to women under age 35 who have insufficient risk to warrant genetic amniocentesis. In addition, only about a third of women over age 35 undergo amniocentesis.[4] Since many pregnant women undergo ultrasonographic examination, it would be very useful to have an easily detectable, reliable ultrasonographic finding, such as nuchal thickening, to identify affected fetuses early enough in the second trimester so that there is time for possible intervention.

A review of the literature reveals very little information about Down syndrome appearances in the second trimester. This is in contrast to the large body of information describing Down syndrome in neonates at term. Hall[1] evaluated 48 infants with Down syndrome at birth and identified 10 cardinal signs that were commonly present. Excess skin at the base of the neck was noted in 80% of children at birth. He noted, however, especially with regard to the facial appearance, that skin edema may be a factor and that prematurely born infants have a less pasty and almost normal skin. This suggests that skin thickening may be less apparent in early fetal life. Stephens and Shepard[8] studied 13 abor-

tuses with amniocentesis-verified trisomy 21 ranging in gestational age from about 17 to 25 weeks and compared them with normal aborted fetuses of similar size. They used Hall and other authors as a source of possible signs that might be detectable in such a young fetus. They found that only the simian crease, clinodactyly, septal heart defects, and small size were relatively common features in the trisomy 21 fetuses as compared with the normal control fetuses. They stated that the other features noted in term infants were less useful for identification of Down syndrome in early pregnancy.

With our autopsy review we were able to confirm that nuchal thickening can be present in the second trimester, but our 18% incidence is not as high as the 80% and 100% incidences noted in Down syndrome infants at term by Hall[1] and Fried[2] or the 36% (four of 11) found in the ultrasonographic series.[4]

At ultrasonography of chromosomally normal fetuses in the second trimester we found nuchal thickening of over 5 mm more commonly than the incidence of one per 1694 that has been reported. In our retrospective survey we found six of 28 (21%) with a false positive finding. Prospectively, we were able to make the nuchal measurement exceed 5 mm in every instance (seven of seven) when we angled the transducer caudally from Reid's baseline. Examination of a midsagittal dorsal ultrasonogram of a fetus explains this pseudothickening (Fig. 2). As the scan plane is maintained on the thalamus but is tilted to include the cerebellum and cisterna magna, the section will include an increasingly thick section of nuchal muscles and skin. This is of concern since the inexperienced observer may easily interpret this to be pathologic thickening, especially if he/she is conscientious enough to deliberately survey the nuchal area for this feature.

It is known that test properties such as sensitivity and specificity remain stable, irrespective of disease incidence. Unfortunately, this is not true for the more clinically useful positive and negative predictive values, which can undergo dramatic change if the same test is applied to populations that have a different incidence of disease. We can, however, calculate the expected performance in these circumstances.[6] As the incidence decreases, the positive predictive value also decreases. In the original ultrasonographic reports the incidence of Down syndrome was 1:155 and the predictive value of a positive test was 80%. However, in the general population where the incidence of Down syndrome is 1:660,[7] a positive test will predict disease in only 48% of instances. For pregnancy in women under age 30, the incidence is 1:1500 (Table I). Here a positive test will predict Down syndrome in only 20% of fetuses. This means that the other 80% or four of five fetuses with the finding will not have Down syndrome. As more information becomes available, these calculations may undergo significant change. Nevertheless, the 80% false positive rate in mothers under age 30 would suggest a more cautious approach than suggested by the previously published reports that urge that mothers be told that their fetus has a probability of having Down syndrome and have their options explained to them on the basis of only the ultrasonographic findings.

In summary, we feel that this potentially useful ultrasonographic sign of Down syndrome should be used with great caution. It is important to remember that the sign has been described only in the early second trimester and should not be used after 20 menstrual weeks. We were able to confirm that nuchal thickening does indeed occur in the second trimester in a small proportion of fetuses affected with Down syndrome. The ultrasonographic sign is as yet somewhat poorly described and it is possible to create false positive images in a significant proportion of chromosomally normal fetuses. In the normal low-risk obstetric population, the observation of the finding is more likely to identify a normal fetus than an abnormal one.

Clinical high-risk designation does not predict excess fetal-maternal hemorrhage

Paul M. Ness, M.D., Michael L. Baldwin, M.T.(A.S.C.P.), S.B.B., and Jennifer R. Niebyl, M.D.
Baltimore, Maryland

During a 5-year period, an enzyme-linked antiglobulin test was used to screen and quantitate fetal-maternal hemorrhage in 789 consecutive D-negative mothers who were delivered of D-positive babies. Six hundred seventy-two patients (85.2%) had no detectable fetal-maternal hemorrhage, and 117 patients (14.8%) had a detectable fetal-maternal hemorrhage. Eight of the 789 (1%) had a fetal-maternal hemorrhage >30 ml and required more than one vial of Rh immune globulin. Two patients with fetal-maternal hemorrhage of 29 and 30 ml also received additional Rh immune globulin. Each case was reviewed for the presence of high-risk features that are thought to predict patients at risk for fetal-maternal hemorrhage. Patients having a cesarean section or complicated vaginal delivery were considered to be in a group at high risk for fetal-maternal hemorrhage, while those with a spontaneous vaginal delivery were considered not to be at risk for fetal-maternal hemorrhage. Thirty-two of 237 patients (13.5%) in the risk group and 82 of 552 patients (15.3%) in the group not at risk had detectable fetal-maternal hemorrhage. The incidence of fetal-maternal hemorrhage for these two groups was not statistically different ($p > 0.50$ by χ^2 analysis). If only patients in the risk group had been screened for fetal-maternal hemorrhage, then five of 10 (50%) who required more than one vial of Rh immune globulin would have been undertreated and at risk for developing anti-D antibodies. In addition, newborn birth weight, Apgar scores, and hematocrits were examined for 13 cases of fetal-maternal hemorrhage of ≥21 ml, and none of these characteristics could be used to predict patients at risk for fetal-maternal hemorrhage. Therefore, no maternal or newborn characteristics could be identified that would reliably predict patients at risk for fetal-maternal hemorrhage. We conclude that all D-negative patients with D-positive babies should continue to be screened for fetal-maternal hemorrhage to identify those patients requiring more than one vial of Rh immune globulin. (Am J Obstet Gynecol 1987;156:154-8.)

Key words: High-risk pregnancy, fetomaternal hemorrhage, Rh immune globulin, enzyme-linked antiglobulin test

The American College of Obstetrics and Gynecology has recommended that screening for excess postpartum fetal-maternal hemorrhage in D-negative mothers who are delivered of D-positive infants be performed only for high-risk pregnancies.[1] This policy has raised much debate concerning the efficacy of screening only selected high-risk pregnancies.[2-4] Previously, a report from our institution examining postpartum blood samples from 186 D-negative mothers with D-positive babies during a 1-year period demonstrated that no clinical or historical factors could predict the patients at risk for any detectable fetal-maternal hemorrhage.[5] This report extends these findings to 789 patients studied prospectively during a 5-year period and examines the risk factors associated with fetal-maternal hemorrhage requiring more than one vial of Rh-immune globulin.

Material and methods

The patients tested were D-negative mothers without anti-D antibodies who were delivered of Rh-positive babies at The Johns Hopkins Hospital from July 1980 through July 1985. No patients were excluded from this prospective study. Clotted blood specimens from the mother and baby were tested for ABO and D, including Du, by standard test tube methods.[6] A postpartum maternal blood sample collected in ethylenediaminetetraacetic acid (EDTA) was used to evaluate fetal-maternal hemorrhage by the enzyme-linked antiglobulin test, which has been previously described in detail.[7, 8] The test involves incubation of anti-D antibodies with the postpartum maternal EDTA blood sample, then the addition of an anti–immunoglobulin G antibody, which is conjugated with the enzyme alkaline phosphatase, and finally the addition of the substrate *p*-nitrophenyl phosphate, which is converted to a yellow

pigment for reading in a spectrophotometer. The blood sample of the patient is compared with a standard curve that contains 0%, 0.25%, 0.5%, and 1% of Rh-positive red blood cells, which corresponds to a fetal-maternal hemorrhage in a 70 kg mother (5000 ml blood volume) of 0, 12.5, 25, and 50 ml of whole blood.

Obstetric charts and a delivery suite log were reviewed to determine the mode of delivery. The mode of delivery was classified into one of three categories: spontaneous vaginal delivery, cesarean section, or complicated vaginal delivery. Delivery was considered complicated when forceps were used, multiple births occurred, abnormal third-trimester bleeding was noted, or fetal death was diagnosed in utero.

Results

Table I shows the fetal-maternal hemorrhage detected in 789 postpartum samples from Rh-negative mothers delivered of Rh-positive babies. Six hundred seventy-two of the 789 samples (85.2%) had no detectable fetal-maternal bleeding. One hundred seventeen of the 789 samples (14.8%) had a detectable fetal-maternal hemorrhage, and only eight of the 789 (1.0%) had bleeding >30 ml. Two samples in the 21 to 30 ml category had a fetal-maternal hemorrhage >25 ml, one of 29 ml and one of 30 ml. These two patients received an additional vial of Rh immune globulin. Table I also shows results from the previous 1-year study as compared with the 5-year study of this report.

Table II shows the number and total percentage of postpartum samples categorized by the amount of fetal-maternal hemorrhage and compared with the type of delivery. The percentage of patients in the three categories of delivery (spontaneous vaginal delivery, cesarean section, and complicated vaginal delivery) was similar for both the detectable and not detectable fetal-maternal hemorrhage groups, respectively: spontaneous vaginal delivery, 73% versus 70%; cesarean section, 19% versus 23%; and complicated vaginal delivery, 8% versus 7%. Table II also shows the number and percentage of babies that were ABO compatible or incompatible with the maternal ABO type. For those with a detectable fetal-maternal hemorrhage and those with no detectable fetal-maternal hemorrhage, the percentages are similar: ABO compatible, 79% versus 78%; ABO incompatible, 21% versus 22%.

Table III compares the amount of fetal-maternal hemorrhage for each type of complicated vaginal delivery or cesarean section. These data show that for any one high-risk group, the majority of patients have no detectable fetal-maternal hemorrhage. For all of these patients, only 32 of 237 (13.5%) had any detectable fetal-maternal hemorrhage. This is not statistically different from the incidence of fetal-maternal hemor-

‡Spontaneous delivery of placenta.

§Premature infant born at about 30 weeks, with transfusion for anemia.

rhage for patients who had spontaneous vaginal delivery without any complications (Table II), where 85 of 552 (15.8%) had a detectable fetal-maternal hemorrhage ($p > 0.50$).

Table IV provides a summary of all 13 patients who had a fetal-maternal hemorrhage of ≥21 ml. Seven of these patients had a spontaneous vaginal delivery without any complicating factors, one patient had twins, and five patients had a cesarean section. The five patients with spontaneous vaginal delivery and bleeding >30 ml all had spontaneous delivery of the placenta. Manual removal of the placenta was not a cause of fetal-maternal hemorrhage in these patients. Birth weight, Apgar scores, and hematocrits were examined for each newborn infant to see if any of these would be indicators of fetal-maternal hemorrhage. Neonatal anemia might have suggested large amounts of fetal-maternal hemorrhage in only two cases, Case No. 13 (hematocrit 33%) at 30 weeks' gestational age and Case No. 6 (hematocrit 29%) with an unusually large fetal-maternal hemorrhage of approximately 168 ml. As shown in Table IV, five of the 10 patients receiving an additional vial of Rh immune globulin would have been missed if only risk groups defined by the American College of Obstetricians and Gynecologists were screened for excessive fetal-maternal hemorrhage.

Comment

The initial report from our hospital used enzyme-linked antiglobulin test to detect and measure fetal-

maternal hemorrhage in 186 patients during a 1-year period.[5] This report extends the study to 789 patients during a 5-year period and includes the 186 patients previously described. The percentage of patients with and without detectable fetal-maternal hemorrhage is similar for the two time periods as shown in Table I. The current study shows that 117 patients (14.8%) had a detectable fetal-maternal hemorrhage and that eight patients (1%) had a fetal-maternal hemorrhage >30 ml. This is similar to results in previous studies that used the acid-elution stain to quantitate fetal-maternal hemorrhage and showed an overall incidence of detectable bleeding to be 14.5% with 1% >30 ml.[9]

The American College of Obstetrics and Gynecology has stated that routine screening for excess fetal-maternal hemorrhage is not recommended but should, however, be performed for all high-risk pregnancies.[1] The American College of Obstetricians and Gynecologists defines high risk to be circumstances such as abruptio placentae, placenta previa, cesarean delivery, intrauterine manipulation (as with twins), or manual removal of the placenta. This report demonstrates that these risk factors are not accurate predictors of any detectable fetal-maternal hemorrhage or, more important, excess fetal-maternal hemorrhage requiring more than one vial of Rh immune globulin. In this study, 237 patients, or 30% of the total, were found to be in an American College of Obstetricians and Gynecologists risk category, either cesarean section or complicated vaginal delivery. However, only 32 of these 237 patients (13.5%) had a detectable fetal-maternal hemorrhage, which is not significantly different from the incidence in the group that was considered not to be at risk, where 82 of 552 patients (15.3%) had a detectable fetal-maternal hemorrhage ($p > 0.50$). These data show that being in an American College of Obstetricians and Gynecologists risk category is not a predictor of fetal-maternal hemorrhage.

Table IV provides a summary of all 13 patients found to have a fetal-maternal hemorrhage of ≥21 ml. If the criteria of the American College of Obstetricians and Gynecologists had been used to determine the population of patients requiring screening for fetal-maternal hemorrhage, four of the eight with a fetal-maternal hemorrhage >30 ml would have been missed and at risk for forming anti-D antibodies because of an inadequate dose of Rh immune globulin. In addition, two of the five patients with fetal-maternal hemorrhage between 21 and 30 ml had bleeding quantitated by the enzyme-linked antiglobulin test to be 29 and 30 ml. Since the reproducibility of the enzyme-linked antiglobulin test is ± 10%, each of these patients was given a second vial of Rh immune globulin. One of these patients was in a risk category (Case No. 13) and the other was not (Case No. 8). Again, if only the patients in risk categories were screened for excess fetal-maternal hemorrhage, then one of these two patients would have been at risk for alloimmunization and subsequent affected pregnancies. Therefore, in this study, a total of five of 10 patients (50%) would have been undertreated if only the criteria of the American College of Obstetricians and Gynecologists were followed.

We also investigated maternal parity, newborn birth weight, Apgar scores, and hematocrit for these 13 patients. These factors, taken singly or in combination, do not reliably predict excessive fetal-maternal hemorrhage. When the normal range for hematocrit[10] at birth is taken to be 53% to 65%, then only five of these newborn infants had hematocrits below the normal range (Cases 6, 8, 10, 12, and 13). Only in Cases 6 and 13 were the hematocrits markedly below normal. In Case 6, the hematocrit of 29% can be attributed to an unusually large fetal-maternal hemorrhage of approximately 168 ml. In Case 13, the fetal-maternal hemorrhage of 29 ml represents a large volume for a low birth weight infant (1480 gm) and accounts for the low hematocrit of 33%. However, as shown by Cases 3, 7, 9, and 11, the normal hematocrits give no indication of the excessive fetal-maternal hemorrhage requiring more than one vial of Rh immune globulin.

In summary, this study shows that there are no reliable indicators to predict patients at risk for fetal-maternal hemorrhage, or specifically at risk for excess fetal-maternal hemorrhage. Following the policy suggested by the American College of Obstetricians and Gynecologists would have resulted in half of the patients (five of 10) in this study being undertreated and at risk for developing anti-D antibodies. Simple, sensitive, and inexpensive methods exist to screen routinely for excessive fetal-maternal hemorrhage. The enzyme-linked antiglobulin test used in this study has the advantage of screening and quantitating with one procedure. The rosette technique as described by Sebring and Polesky[11] is a simple and inexpensive screening procedure that, if positive, can then be followed by a quantitative procedure. In the near future, other techniques that are sensitive, objective, and automated can be adapted to meet the medical requirements for fetal-maternal hemorrhage screening.

We therefore conclude that there are no medical or economic reasons not to screen all D-negative mothers delivered of D-positive babies for excess fetal-maternal hemorrhage. The availability of acceptable screening procedures would suggest potential liability if a patient develops anti-D antibodies in the absence of adequate screening. Finally, we would question whether any criteria for screening could be adopted that would result in screening of all indicated patients. Unless the criteria for which patients to screen are rigidly enforced and a suitable monitoring system can be implemented, many

patients will not receive screening even if they meet the criteria.

Endometrial blood flow measured by xenon 133 clearance in women with normal menstrual cycles and dysfunctional uterine bleeding

Ian S. Fraser, M.D., Gay McCarron, R.N., Brian Hutton, M.Sc., and Daniel Macey, Ph.D.
Sydney and Camperdown, Australia, and Oxford, England

Endometrial blood flow was measured through the menstrual cycle in nonpregnant women (28 studies of 17 women with normal menstrual cycles and 32 studies of 20 women with dysfunctional uterine bleeding) with use of a clearance technique in which 100 to 400 μCi of the γ-emitting isotope, xenon 133 in saline solution was instilled into the uterine cavity. The mean (± SEM) endometrial blood flow in normal cycles was 27.7 ± 2.6 ml/100 gm/min, with a significant elevation in the middle to late follicular phase, followed by a substantial fall and a secondary slow luteal phase rise that was maintained until the onset of menstruation. There was a significant correlation between plasma estradiol levels and endometrial blood flow in the follicular but not the luteal phase. Blood flow patterns in women with ovulatory dysfunctional bleeding were similar to normal, except for a significantly lower middle follicular rate. Women with anovulatory dysfunctional bleeding exhibited exceedingly variable flow rates. (AM J OBSTET GYNECOL 1987;156:158-66.)

Key words: Endometrium, blood flow, menstrual cycle, dysfunctional uterine bleeding, xenon clearance

Several investigators have devised different approaches to the measurement of human myometrial and endometrial blood flow with use of inert gas clearance.[1-5] Most studies have concentrated on myometrial blood flow, and virtually nothing is known about absolute changes in human endometrial blood flow during normal or abnormal menstrual cycles.

The only previous study that has used a technique capable of giving a measure of the absolute rate of blood flow in human endometrium demonstrated a fall in flow when in the standing position compared with the supine one.[3] These investigators used a technique of intrauterine xenon 133 clearance, which has been explored and validated further by us.[6]

Preliminary information on relative changes in endometrial blood flow during the menstrual cycle has

been presented by Markee[7] from his work on endometrial ocular autotransplants in rhesus monkeys and by Prill and Götz[8] using a heat clearance technique in women. Neither of these methods can give a measure of absolute rates of flow, and the heat clearance technique cannot be accurately calibrated from day to day.

This report describes the first study of changes in absolute blood flow in human endometrium at different stages of the normal menstrual cycle and in a group of women with dysfunctional uterine bleeding.

Material and methods

Endometrial blood flow measurement was carried out with use of an intrauterine ^{133}Xe clearance technique. The theoretic considerations of inert gas clearance of this type from tissue have been well described and evaluated by Kety[9] and have been applied by a number of investigators to the study of human myometrial[1-5] and endometrial blood flow.[3] Testing of theoretic considerations has been described more fully (Fraser IS, McCarron G, Hutton BF, Macey D. An evaluation of two inert gas clearance techniques for measurement of endometrial blood flow in women. Unpublished observations).

^{133}Xe (100 to 400 μCi) was instilled through a fine and moderately pliable catheter (Portex Instruments, Hythe, Kent, England; size 4FG, external diameter of 1.34 mm) in a small volume (0.05 to 0.1 ml) of normal saline solution into the uterine fundus. Steady uptake into endometrial tissue and clearance into the venous circulation are directly related to endometrial blood flow. Over 90% of the gas is then eliminated from the body in one passage through the lungs. The removal of radioactivity from the uterine cavity was detected by an external gamma camera (Searle Pho-Gamma 4, with a 28 cm field and a high sensitivity collimator) and recorded and analyzed with use of a computer interfaced with the gamma camera. The clearance curves were analyzed into two or three single exponential components on log-linear scales. The flow rates in each compartment were calculated from the following equation, assuming a tissue/blood partition coefficient for ^{133}Xe of 1.0[10] and a specific gravity for endometrium of 1.0:

$$F = 100k \text{ ml}/100 \text{ gm/min}$$

where $k = 0.693 \div t_{1/2}$ and $t_{1/2}$ = the half-time of the exponential in minutes. The relative sizes of each of

the compartments as a percentage of total tissue mass (m′% and m″%) were calculated by back extrapolation of the exponents to time zero to obtain the initial distribution of counts to each compartment (Ao′ and Ao″):

$$\frac{Ao'}{Ao''} = \frac{F' \times m'\%}{F'' \times m''\%}$$

and the mean endometrial flow (F) from the relation:

$$F = (F' \times m'\%) + (F'' \times m''\%)$$

Experimental data from ewes[6] indicated that the mean flow with use of both compartments gave a more accurate assessment of total endometrial flow than use of any single compartment flow on its own. However, there is still considerable controversy as to the significance of different compartments, which are therefore reported separately here.

Analysis was carried out with use of a computer (Digital Equipment Corporation, Model PDP 11/34 Gamma 11) and modified iterative function minimization program[11] for fitting a multiexponential curve by the least squares method. The formula for the washout curve was as follows:

$$A(t) = Ao' \exp(-k't) + Ao'' \exp(-k''t)$$

where A is the activity at the time t, and Ao′, Ao″, k′, and k″ are the unknown constants to be estimated for a two- or three-component exponential.

The analysis of the curves obtained assumes a bimodal distribution of blood flow into two or three homogeneously perfused compartments that are arranged in parallel. After conversion to a log-linear scale, analysis involves initial identification of the slowest component (after background subtraction), which is then subtracted from the original raw data curve to leave the faster component. In occasional experiments an ultrafast third component was identified when the second component was subtracted. The existence of different components or compartments points to the existence of portions of endometrial tissue with different blood flow rates. The influence of small air bubbles

in the injection, volume of injection fluid, and repeated installations on clearance curves have all been studied in detail and have not been found to interfere significantly with the flow measurements (Fraser IS, McCarron G, Hutton BF, Macey D. An evaluation of two inert gas clearance techniques for measurement of endometrial blood flow in women. Unpublished observations).

Subjects studied included 17 women with normal menstrual cycles (Table I) and 20 women with dysfunctional uterine bleeding (6 anovulatory) (Table II). These women were studied at different stages of the menstrual cycle, and 15 were studied on more than one occasion (seven normal cycles and eight with dysfunctional uterine bleeding). Dysfunctional uterine bleeding has been defined as excessively heavy, excessively prolonged, or excessively frequent uterine bleeding in the absence of recognizable pelvic or generalized medical disease or pregnancy.[12] All subjects enrolled into this study gave a convincing history of menorrhagia.

Almost all subjects also had plasma estradiol and progesterone levels measured at the time of blood flow studies, and most had several samples taken at other stages in the same cycle. All women kept an accurate note of data of each preceding and succeeding menstrual period, and some maintained basal body temperature and vaginal mucus charts. A combination of these pieces of information permitted dating of each blood flow measurement to an idealized 28-day menstrual cycle, except in those women with a history of anovulatory dysfunctional uterine bleeding.

Results

^{133}Xe washout half-times and supine endometrial blood flow calculations for each subject are summarized in Tables III and IV. The overall mean (±SEM) endometrial blood flow in women with normal cycles was 27.7 ± 2.6 ml/100 gm/min when all measurements were considered together. Control subjects and women with ovulatory and anovulatory dysfunctional uterine bleeding have been considered separately in Table V according to this stage of the cycle. Although numbers in each group are small, there does not appear to be much difference between women with normal menstrual cycles and those with ovulatory dysfunctional uterine bleeding (Figs. 1 and 2). However, blood flow in normal women in the middle follicular phase (days 8 to 12) was significantly higher than in the women with ovulatory dysfunctional uterine bleeding (39.6 and 25.2 ml/100 gm/min; $t = 2.274$, $p < 0.05$). One woman with

Table V. Endometrial blood flow measurements at different stages of the menstrual cycle in women with normal cycles or dysfunctional uterine bleeding

	Early follicular days 1-7	Middle follicular days 8-12	Peri-ovulatory days 13-16	Early luteal days 17-21	Middle luteal days 22-25	Pre-menstrual days 26-28	Persistent follicular (anovulatory)
Normal cycles	19.3 (n = 6)	39.6 (n = 8)	12.5 (n = 4)	23.5 (n = 3)	32.8 (n = 4)	30.1 (n = 3)	–
Ovulatory dysfunctional uterine bleeding	17.8 (n = 3)	25.2 (n = 9)	14.1 (n = 2)	20.6 (n = 3)	33.0 (n = 4)	38.8 (n = 3)	–
Anovulatory dysfunctional uterine bleeding	11.6 (n = 1)	40.9 (n = 2)	–	–	–	–	37.9 (n = 5)

ovulatory dysfunctional uterine bleeding had a high rate of flow (51.8 ml/100 gm/min) on the day before menstruation, but others with dysfunctional uterine bleeding were in the same range as control subjects in the premenstrual period.

The number of women with anovulatory dysfunctional uterine bleeding was too small to make any comment except that exceedingly variable blood flows were recorded and these overlapped with normal levels.

Women with normal cycles and ovulatory dysfunctional uterine bleeding had an obvious cyclical variation in endometrial blood flow with high levels in the middle to late follicular phase which fell substantially around ovulation. A secondary rise occurred through the early and middle luteal phases and was maintained until the onset of menstruation. In two women (C13 and OD3) measurements were carried out just after the onset of premenstrual spotting and a few hours before the onset of full flow. In both these cases endometrial flow was still maintained at a fairly high level (27.5 and 25.0 ml/100 gm/min). Later in menstruation and during the early follicular phase flow was slower.

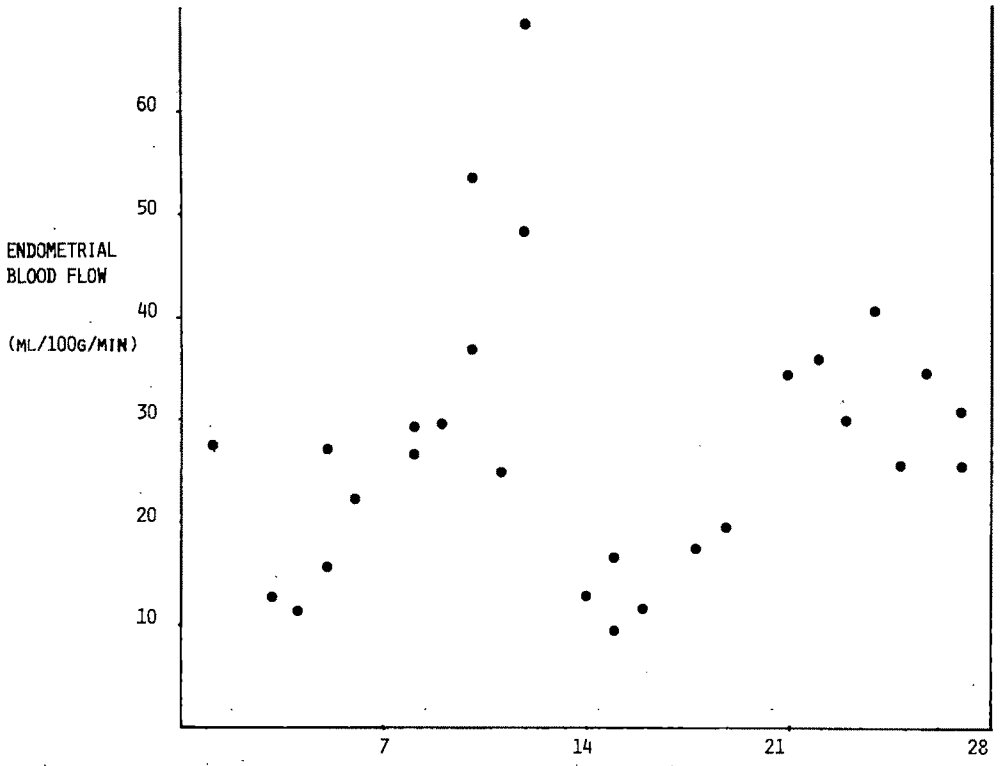

Fig. 1. Endometrial blood flow (ml/100 gm/min) measured using ^{133}Xe clearance at different stages of the menstrual cycle in women with normal cycles. Data have been adjusted to fit into an idealized 28-day menstrual cycle.

Only six examples of three component curves were recorded, which occurred in both dysfunctional uterine bleeding groups as well as in normal cycles. There did not appear to be any particular pattern to their occurrence, and mean flows were quite variable (17.0 to 68.1 ml/100 gm/min).

A clear correlation between plasma estradiol levels and endometrial blood flow was recorded for all studies undertaken when progesterone levels were <1 ng/ml ($r = 0.622$; $n = 31$) (Fig. 3) and for women with normal cycles when progesterone was <1 ng/ml ($r = 0.760$; $n = 13$). This correlation between plasma estradiol and endometrial blood flow was lost when progesterone was elevated (total subjects: $r = 0.016$; $n = 25$). No correlation between plasma progesterone levels and endometrial blood flow was found for luteal phase studies (total: $r = 0.073$; $n = 25$). This poor correlation was particularly obvious when endometrial blood flow did not fall substantially during the premenstrual period at a time when estradiol and progesterone were falling rapidly.

Comment

Most previous work on genital tract blood flow in nonpregnant women has been directed toward study of myometrium, myomas, endometrial cancer, amenorrhea, dysmenorrhea, and changes in posture, and no previous systematic studies have been carried out in normal and abnormal cycles or in relation to menstruation. This investigation has provided the first assessment of changes in absolute blood flow in human endometrium through the menstrual cycle, as well as in women with dysfunctional uterine bleeding.

Cyclical changes in endometrial blood flow have been clearly demonstrated, with high levels in the middle to late follicular phase, a large fall at around ovulation, and a secondary luteal phase rise that was maintained until menstruation. The preovulatory measurements showed a positive correlation between circulating levels of estradiol and endometrial blood flow. This correlation was lost during the luteal phase. The major fall in blood flow at around ovulation seemed to slightly precede the midcycle rise in progesterone. Unfortunately, the progesterone assays used in the study were not reported sufficiently accurately in the lowest part of the range to exclude a very small rise in progesterone in two subjects (C14 and OD8) who had low blood flow levels at days 12 and 14. Other factors than plasma estradiol and progesterone levels must influence endometrial blood flow, at least during some stages of the cycle.

In the latter part of the luteal phase when luteolysis was occurring, there was no evidence of any related fall in endometrial blood flow. In fact, blood flow was still

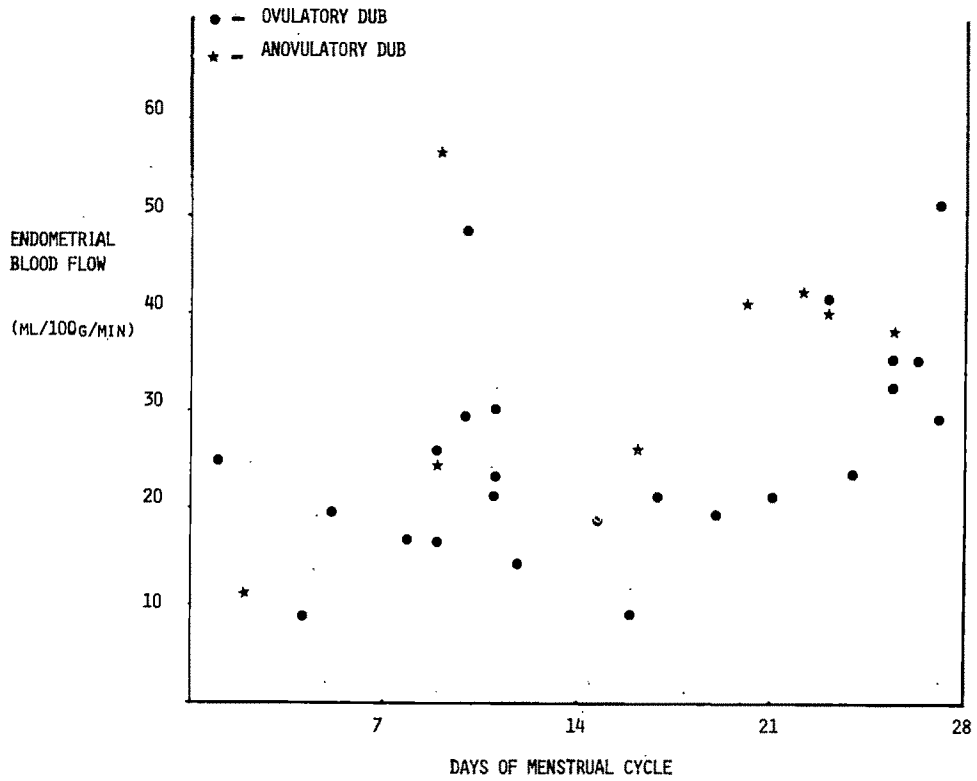

Fig. 2. Endometrial blood flow (ml/100 gm/min) measured using ^{133}Xe clearance in women with ovulatory and anovulatory dysfunctional uterine bleeding. Data for women with ovulatory dysfunctional uterine bleeding have been adjusted to fit into an idealized 28-day menstrual cycle.

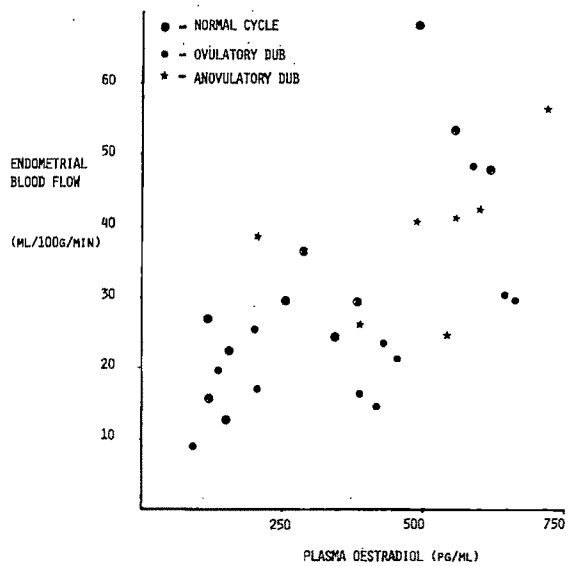

Fig. 3. Comparison of endometrial blood flow with plasma levels of estradiol in women with normal cycles and ovulatory or anovulatory dysfunctional uterine bleeding. Only follicular phase measurements (plasma progesterone level of <1 ng/ml) have been included.

relatively high (27.5 and 25.0 ml/100 gm/min) in two subjects who were experiencing premenstrual spotting and who began bleeding heavily within 3 to 4 hours.

Two previous studies have provided evidence of the occurrence of cyclical changes in endometrial blood flow during the menstrual cycle. Markee[7] studied endometrial autotransplants in the anterior chamber of the eye of rhesus monkeys and measured blood flow by a stroboscopic technique that assessed the speed of movement of red cells through stromal capillaries in millimeters per second. Prill and Götz[8] used a heat clearance probe technique to study cyclical changes in human endometrial blood flow in $10^{-4}cal \cdot cm^{-1} \cdot sec^{-1} \cdot °c^{-1}$, although this type of technique cannot be exactly recalibrated from one day to the next. It is also pertinent to note that an intrauterine probe may cause artificial changes in local blood flow. A comparison of the pattern of cyclical changes demonstrated by these two groups of investigators with the present ^{133}Xe study is shown in Fig. 4. All studies showed a preovulatory peak with a postovulatory fall and a secondary rise in the luteal phase, although clear differences are also apparent. The ^{133}Xe clearance technique demonstrated a much more marked periovulatory fall in endometrial flow with a very slow rise in the luteal phase. With the heat clearance technique a slow premenstrual rise in flow was also seen and this continued until days 2 to 3 of menstruation. In the rhesus monkeys a marked premenstrual fall in flow was seen. Much of our current understanding of the morphology of menstruating endometrium is based on the rhesus monkey studies of

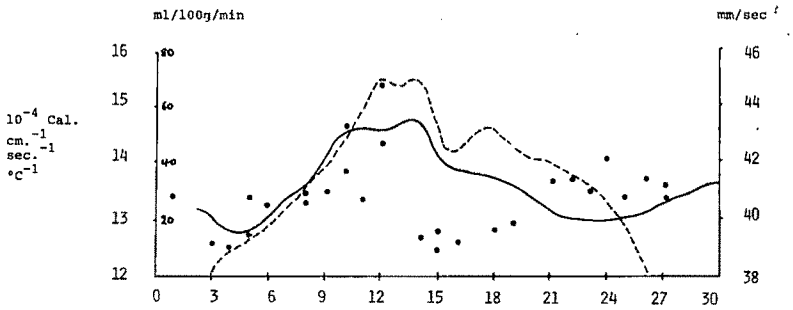

Fig. 4. Comparison of endometrial blood flow at different stages of the menstrual cycle measured by ^{133}Xe clearance in normal women (ml/100 gm/min) and compared with the data of Markee[7] in rhesus monkeys (mm/sec; *dotted line*) and Prill and Götz[8] using a heat clearance technique in women (10^{-4}cal · cm^{-1} · sec^{-1} · °C^{-1}; *continuous line*).

Markee,[13] especially with respect to the occurrence of dramatic vasoconstriction in the endometrium just before and at the onset of bleeding. Our study and that of Prill and Götz[8] suggest that this may not occur, at least to the same extent in humans, in which case the local coagulation mechanisms studied by Christiaens et al.[14] may play a more dominant role in the maintenance of hemostasis in the human uterus. Nevertheless, in pathologic conditions such as spasmodic dysmenorrhea other factors such as excessive uterine contractions may produce substantial falls in endometrial blood flow during menstruation.[15] There is also some histologic evidence that arteriolar vasoconstriction may sometimes occur in human late luteal phase endometrium.

Only one previous investigation has reported absolute flow measurements in human endometrium.[3] This study used a different technique of clearance analysis which may not always be appropriate for uterine blood flow studies.[5] However, this study does report the first measurements of absolute flow in human endometrium, and although the mean level (17.8 ml/100 gm/min; range, 13.5 to 29.0) is lower than the present study (27.7 ml/100 gm/min); range, 9.1 to 68.1), the range overlaps greatly. It is of interest that all the ^{133}Xe studies of blood flow in human (nonpregnant) myometrium are in the same range of 3 to 40 ml/100 gm/min. This is very similar to the range of measurements of endometrial flow, although it has been demonstrated in sheep that endometrial and myometrial flow may show large independent variations.[6] Myometrial blood flow in pregnancy is very much higher (77 ± 2.5 ml/100 gm/min; mean ± SEM).

Many aspects of endometrial function are poorly understood, and this applies particularly to endometrial blood flow. Blood flow is clearly important for nourishment of the endometrium and may vary greatly at different levels in the tissue and under the influence of different hormones. There is a need for a more systematic assessment of serial change in individual women, of changes during the cycle, and of changes in different hormonal states (for example, during exogenous hormonal treatment) as well as for a comparison with methods that describe different aspects of endometrial blood flow such as heat clearance[15] and krypton 85 clearance (Fraser IS, McCarron G, Hutton BF, Macey D. An evaluation of two inert gas clearance techniques for measurement of endometrial blood flow in women. Unpublished observations). This ^{133}Xe method is the only approach that could be used at present to assess the effect of hormones and other substances such as prostaglandins, prostaglandin inhibitors, catecholamines, histamines, angiotensin, and various other drugs on absolute changes in endometrial blood flow. Any or all of these may have implications for variations in blood loss at the onset of menstruation. Modern computer analysis techniques could be developed to provide more precise information about all these changes and a better knowledge of this poorly understood aspect of endometrial physiology and pathophysiology. It seems unlikely that techniques of this type will offer any early prospect of aiding or improving the precision of clinical diagnosis or management.

Routine hepatitis screening in adolescent pregnancies: Is it cost effective?

Ann M. Wetzel, M.D., and Donna S. Kirz, M.D.
Chicago, Illinois

In most obstetric centers routine serum screening for hepatitis B is not part of standard prenatal care. This study was designed to determine whether hepatitis B screening is cost effective for routine prenatal testing. In a prenatal population of 585 adolescents the cost-benefit ratio of hepatitis B screening was compared with that of routine syphilis screening. Eight positive results were detected, with a cost of $1755 per positive case. This compared favorably with the frequency and cost of detection of syphilis in the same population. Routine hepatitis B screening is recommended for consideration in similar prenatal populations. (AM J OBSTET GYNECOL 1987;156:166-9.)

Key words: Hepatitis, adolescents, pregnancy, cost-effective screening

During the past several decades, the development and widespread use of hepatitis B screening have increased an awareness of this serious disease. Programs have been initiated to screen all blood donors and thus prevent the spread of hepatitis B by blood transfusion. Another major route of transmission of the disease is vertical transmission from mother to infant in the perinatal period. In the United States this route has not yet received as much attention and investigation as has transmission by blood transfusion.

In some countries in Asia, hepatitis B is a major maternal health problem. As much as 10% of the population may be carriers.[1] Therefore screening for hepatitis B is part of routine prenatal care. In the United States, hepatitis B screening is routine for prenatal patients of Chinese and Southeast Asian extraction. Among other racial groups, guidelines are much les clear. Whether the disease is sufficiently common t justify routine prenatal screening has not yet been in vestigated.

This study was designed to answer that question. I an adolescent prenatal population we determined th incidence of hepatitis B and compared the cost of hep atitis B screening with that of the universally accepte routine VDRL screening.

Material and methods

Rush-Presbyterian-St. Luke's Medical Center is large private university hospital located on Chicago' West Side. There is a delivery service of approximatel 3200 women. To care for the health needs of pregnan adolescents, the Adolescent Family Center was estab lished. The Adolescent Family Center patients are pre dominantly inner-city, black, poor, and mostly on publi aid. Care is provided by a team of nurse-midwives social workers, and a nutritionist, with supervision o staff obstetricians.

From the Department of Obstetrics and Gynecology, Rush-Presbyterian-St. Luke's Medical Center.

Group 1: Patients presenting before 1983, screened with hepatitis B surface antigen alone. Group 2: Patients presenting after 1983, who underwent full serologic screening.

From 1981 to mid-1983, a hepatitis B surface antigen test was obtained for all patients initiating care at the Adolescent Family Center clinic. Because of the number of positive results obtained, it was decided to study hepatitis B in this population in greater depth. Accordingly, from late 1983 until February 1985 all patients were screened at the first visit with a hepatitis profile consisting of at least a hepatitis B surface antigen and a hepatitis B surface antibody. Additionally, since the beginning of 1984, hepatitis B e antigen and hepatitis B e antibody have also been evaluated.

Tests were performed either by Mason-Barron Laboratories or the laboratory of Rush-Presbyterian-St. Luke's Medical Center. Hepatitis B surface antigen was determined by an enzyme-linked immunosorbent assay or radioimmunoassay. Other antigen and antibody tests were performed by radioimmunoassay at Rush-Presbyterian-St. Luke's. All patients also had a rapid plasma reagin test performed at the initial prenatal visit. If this was positive, a fluorescent treponemal antibody absorption test was performed to confirm syphilis infection. A rapid plasma reagin test was also routinely done at 32 weeks and on admission to the hospital for delivery.

Any positive results obtained were reviewed by the attending obstetricians supervising the clinic and appropriate treatment was initiated. In the case of positive hepatitis B surface antigen results the nursery was informed so that treatment of the infant could be carried out.

The data obtained were analyzed by determining the incidence of positivity for both hepatitis and syphilis. The cost of tests was established by the laboratory at Rush-Presbyterian-St. Luke's Medical Center. Subgroups were analyzed by χ^2 analysis to examine the significance of presumed risk factors.

Results

Data were obtained for 585 patients. Of these, 361 presented before mid-1983 and composed the first group. The remaining 224 had the more complete hepatitis profile performed, including hepatitis B e antigen and hepatitis B e antibody (group 2).

The age range was 12 to 19 years; 85% were between 15 and 18. The mean and SD of age, gravidity, parity, and pregnancy outcome, as represented by fetal weight and Apgar scores, are given in Table I. It can be seen that the two groups differed very little. The population was overwhelmingly unmarried. Of those who gave a marital status 95.5% were unmarried. There were 94% black, 2% Caucasian, and 4% Hispanic women. These percentages were essentially the same in both groups.

Table II. Hepatitis profile and rapid plasma reagin test results in group 2

	Positive results	
Test	*Frequency*	*Percentage*
Hepatitis B surface antigen	3	1.339
Hepatitis B surface antibody	18	8.072
Hepatitis B e antigen	2	1.005
Hepatitis B e antibody	8	3.980
Rapid plasma reagin	1	0.450

Out of the entire population eight patients were found to have positive hepatitis B surface antigen titers. This was an incidence of 1.37%. The cost of a hepatitis B surface antigen titer at the laboratory performing these tests is $24 per patient. In this population, therefore, the cost to detect each case was $1755.

In comparison, a positive rapid plasma reagin test result was found in six patients, for an incidence of 1.03%. One of these was felt to be a biologic false positive test result, due to intercurrent chickenpox. As the cost of a rapid plasma reagin test was only $10.50, the cost to detect each positive result was $1023.75. However, if only the true cases of syphilis are counted, the cost was $1228.50. According to standard protocol, the rapid plasma reagin test was also obtained at approximately 32 weeks' gestation and at delivery. As no new cases were detected at these times, the total cost for each case of syphilis detected reached $3685.50.

In the group that had a complete hepatitis profile, three positive hepatitis B surface antigen titers were found in 224 patients (see Table II). The incidence is thus very similar to that of the overall group, 1.34%. However, as a complete screen costs $80, the cost of detecting each case was $5973.33. Eighteen patients

were found to have hepatitis B surface antibody present, indicating past hepatitis infection and subsequent immunity. Thus 21 patients either had hepatitis B at that time or had been exposed to it in the past, for an incidence of 9.4%. The presence of the e antigen was also evaluated in this group. Predictably no patient who did not also have positive results for hepatitis B surface antigen showed the presence of e antigen. Of the three patients with positive results for hepatitis B surface antigen, two demonstrated e antigen. The third patient had antibody to the e antigen.

Of the eight cases of hepatitis B detected by routine screening tests, no patients had clinical jaundice or other symptoms suggestive of the diagnosis. One patient gave a history of previous diagnosis as a chronic carrier of hepatitis B. The other seven patients denied any history of hepatitis B exposure.

In the entire population of 585, nine patients gave a history of hepatitis. One of those, as mentioned above, was a chronic carrier. Four of the others stated that they had hepatitis B, while the remaining four were unsure. Six of these eight had complete serologic screening. Only two of these patients had serologic evidence of having had hepatitis B in the past. Interestingly, two of the patients with negative screens insisted that they had previously had hepatitis B.

Analysis of risk factors. Several of the known risk factors related to increased incidence of hepatitis B were also examined. None of the patients in the clinic admitted to intravenous drug abuse, so this risk factor could not be analyzed. Relatively few patients fell into each of the other risk categories. Eighteen patients had a history of blood transfusion, but none of the transfused patients were found to be infectious. Of the six who had hepatitis B testing done, one had hepatitis in the past as demonstrated by the presence of hepatitis B surface antibody. The incidence of hepatitis B in the transfused group was not significantly increased by χ^2 analysis.

Six patients had tattoos noted on physical examination. None of these had active hepatitis B; however, three of the six had serologic evidence of hepatitis B in the past. Of the six tattooed patients in the first group, one had active hepatitis. The increased incidence of past or present hepatitis B in the group 2 patients was statistically significant by χ^2 analysis, with a value of 11.98, $p < 0.01$. Analysis was not valid for group 1 because of the small incidence of both active hepatitis and tattoos.

Ten patients lived in institutional settings. None of them had active hepatitis; however, three of the patients had evidence of hepatitis B in the past. The χ^2 analysis showed this to be a highly significant difference, with a value of 15.4 ($p < 0.001$).

Patients who gave a history of either syphilis, gonvestigated. A total of 92 patients gave such historie Three of these patients had active hepatitis B, and fou had evidence of past infection. In the entire populatio with a past history of sexually transmitted diseases, th incidence of active hepatitis B was slightly increasec This increase was not statistically significant.

Comment

How serious a problem is hepatitis B in pregnancy A mother infected in the third trimester of pregnanc or who is a chronic carrier with a positive e antigen ha approximately a 90% chance of infecting her newbor infant.[3] Although transplacental infection does occu existing information appears to indicate that this is rare occurrence. It develops in about 5% of cases.[1] Most infections occur during birth or during the im mediate postpartum period. Although exposure to ma ternal blood and secretions is thought to be the rout of infection, cesarean section does not decrease the ris of infection.[4] Hepatitis B virus is also present in breas milk, although opinion is divided as to whether this i a significant route of infection.[1, 5]

Mothers who are chronic carriers have less of a ris of passing hepatitis B on to their infants compared wit those with acute hepatitis B. Variation in infectivity i related to the percentage of chronic carriers who hav e antigenemia. This varies from 10% to 71% of carrier but in general is higher in younger carriers, that is, th childbearing age group.[6, 7] If the mother has e antige nemia, the chance that her child will be infected is abou 90%; if she has e antibody, it is <10%.[6] Most of th infants infected at birth do not develop acute hepatitis Those rare infants that do so may die of fulminant live failure. Of the infants infected, 80% to 90% will becom chronic carriers.[2] Thus perinatal infection increases th pool of chronic carriers who will continue to expos others to hepatitis B during their entire lifetimes.

Although chronic carriers may have no obvious ill ness, they do not escape the effects of the hepatitis l virus. Studies indicate a higher incidence of chroni liver disease, including cirrhosis and liver failure, i hepatitis B carriers.[8] Some evidence also suggests tha they are at increased risk for hepatocellular carcinoma Thus these babies not only pose an immediate and con tinuing risk to others but may have an appreciabl shortened life span themselves.

Undetected cases of hepatitis B in prenatal patient also pose danger to hospital personnel. Because of th nature of labor and delivery, nurses and physicians ma have extensive exposure to blood and bodily secretion of a patient. Even roommates, who would not ordinaril be in danger of contracting hepatitis from a fellow pa tient, may be exposed via the shared bathroom in patient whose lochia is infectious.

Increasing concern for cost-effectiveness has mad

out documentation of their yield. This approach has its difficulties, however, in that a value cannot be assigned to human life. Hepatitis contracted in the neonatal period clearly can shorten life span, even if the infant does not experience an acute episode of hepatitis. What value can we place on the lives of these infants?

One approach is to compare routine hepatitis screening with an already accepted and widely used screening test. If we are willing to spend nearly $4000 to detect each case of syphilis, perhaps less than $2000 is reasonable for each hepatitis case detected.

It must be noted that other methods of disease detection would be relatively ineffective in diagnosing these cases of hepatitis. Traditionally, the history and physical examination are the basic screening tests for underlying diseases. None of the eight patients with positive hepatitis test results in this study would have been detected by physical examination and only one by history. The lack of specificity of history is additionally demonstrated by the finding that only one of nine patients giving a history of hepatitis was infectious. Nor can the lack of symptoms in these patients be attributed to chance; previous studies have shown that up to 60% of cases of hepatitis B are asymptomatic.[9] This is confirmed in the present study as well. Six patients gave a history of hepatitis, and only two of these had evidence of having had hepatitis B, for an incidence of 0.89%. Serologic testing of the general population, however, demonstrated a true incidence of 9.4%. This would indicate that only 10% of the patients who had hepatitis B were previously diagnosed as such.

Factors that are known to increase the risk of hepatitis B infection include intravenous drug abuse, tattoos, and blood transfusion.[9] In addition, because of the possibility of sexual transmission, patients with a history of other sexually transmitted diseases may be at increased risk.[10] Institutionalized people, whether in prison or in homes for the retarded, also have a greater risk of hepatitis B.[11] One possible approach to the problem of detecting the most cases of hepatitis B at the lowest cost would be to target these groups for more intensive screening. In this sample, selecting subgroups at higher risk to test also would have been ineffective. Part of this failure was due to the small number of positive cases, which made statistical analysis impossible in some of the subgroups. However, even with these small numbers, the presence of tattoos and institutional living were clearly linked with exposure to hepatitis. Patients with a history of sexually transmitted diseases also had increased risk. Identification of these subgroups did not help to detect infectious patients and thus detect infants at risk. The patients with the risk factors were more likely to have had hepatitis B in the past rather than to have active hepatitis. The fact that risks did not seem to be increased in the population that had received transfusions may be due to the young age of the population. They would have been transfused after widespread screening of blood donors for hepatitis B was initiated in this country, markedly reducing the risk for contracting this type of hepatitis from banked blood.

Screening for hepatitis B in this entire population therefore would seem to be the only way to detect the majority of active cases during pregnancy. While the full hepatitis screen performed in the second group in our study gave added insight into the problem in a study situation, it is clearly not necessary in clinical practice. A single hepatitis B surface antigen value, preferably obtained in the third trimester, would seem to be of value in the management of patients of this population. A test done at this time had less chance of missing a case of hepatitis contracted late in pregnancy, and if a positive test result for hepatitis B surface antigen is found it is likely to persist to term. In cases of positive results, further screening may be done to clarify e antigen status and attempt to differentiate chronic carriers from those having acute episodes of hepatitis.

This recommendation can be generalized to include similar patient populations: inner-city, adolescent, predominantly black, low socioeconomic class. Generalization to populations of different socioeconomic class or living situation cannot be justified at this time. Investigation of these populations might be indicated in the future to further define this problem.

Cardiac output response to prostaglandin E_2–induced abortion in the second trimester

Donald C. Willis, M.D., Donald Caton, M.D., J. Patrick Levelle, M.D., and Tina Banner, R.N.

Gainesville, Florida

Maternal cardiac output changes were evaluated in 10 patients undergoing second-trimester abortion induced by prostaglandin E_2 suppositories. The peak cardiac output increased by an average of 64.5% above preinduction values. This is similar to the percent increase described during oxytocin-induced labor at term. Inasmuch as resting cardiac output tends to be higher in midpregnancy than at term, absolute values during prostaglandin E_2 induction were higher than those observed in laboring term patients. (Am J Obstet Gynecol 1987;156:170-3.)

Key words: Prostaglandin E_2, prostaglandin, cardiac output, elective abortion, labor, pregnancy, cardiac

Prostaglandin E_2 from vaginal suppositories, effective for use in second-trimester abortion, is known to be absorbed systemically.[1] Whether the absorbed drug induces cardiovascular effects in pregnancy is not known but is a pertinent question in view of the potential use in patients with cardiovascular disease. A relative contraindication for the use of prostaglandin suppositories in pregnancy includes women with hypertension or known cardiovascular disease.[2, 3]

Hemodynamically, the most significant cardiovascular alteration observed during pregnancy is the increase in cardiac output. In the past, cardiac output determinations in otherwise healthy pregnant women have been limited by the invasiveness of the procedure. Recently, Doppler determinations of cardiac output have been shown to correlate with the thermal dilution method in nonpregnant subjects ($r = 0.94$, 0.97, and 0.94).[4-6] The present study uses this noninvasive Doppler technique to measure cardiac output response in prostaglandin E_2–induced abortions.

Material and methods

Ten women treated with prostaglandin E_2 vaginal suppositories (Prostin E_2, Upjohn) for midtrimester abortion were included in this investigation. The study was approved by the Institutional Review Board, and informed consent was required for inclusion. Gestational age ranged from 15 to 23 weeks. Three of the 10 abortions were for fetal death, and the others were for medical indications. Patient profiles are listed in Table I.

Three of 13 patients were excluded from the study. Patient No. 6 (Table I) was taking digoxin for Wolff-Parkinson-White syndrome. Patient No. 8 requested continuous epidural analgesia for relief of pain. This form of analgesia has been shown to limit the increase in cardiac output observed in laboring women at term.[7] Patient No. 9 was known to be hypertensive and was treated with methyldopa before induction; she required intravenous hydralazine for blood pressure control during the abortion. Since hydralazine can increase cardiac output, this patient was excluded from the study.[8]

Cardiac output was determined by an ultrasonic Doppler computer (Ultracom, Lawrence Medical Systems, Inc.), a technique that calculates cardiac output by multiplying measurements of aortic blood velocity by aortic diameter. The smallest diameter of the ascending aorta was measured by A-mode echocardiography. Ascending aortic blood velocity was determined by continuous-wave Doppler. Since the aortic root diameter does not change significantly between systole and diastole, cardiac output was then calculated by the Ultracom instrument with use of systolic velocity, cross-section area of the aorta (computed from aortic diameter), and heart rate. Each cardiac output was obtained by taking the average of at least three separate measurements obtained within a 2-minute period. Baseline measurements were obtained before induction and approximately every 90 minutes thereafter. All cardiac output determinations were performed by one of us.

Cardiac output was measured with patients in a 15-degree semirecumbent position because the left lateral position makes Doppler measurements technically

§Fetal death occurred 3 to 4 weeks before abortion.

more difficult to perform. A change in body position during midpregnancy (20 to 24 weeks) causes only a small change in cardiac output (8%),[9] so measurements with the patient semirecumbent were considered reliable.

In midpregnancy, prostaglandin administration is associated more with an increase in uterine tone than with more frequent rhythmic contractions.[10] It was therefore difficult to time cardiac output determinations with uterine contractions. When it was clinically apparent, cardiac output was measured between contractions.

Prostaglandin E_2 vaginal suppositories, 20 mg, were inserted every 3 to 4 hours. Analgesia was provided with a combination of promethazine, 25 mg, and either intravenous meperidine hydrochloride, 25 to 50 mg, or butorphanol (Stadol, Bristol Laboratories), 1-2 mg. Patient No. 8, not included in this study (Table I), received continuous epidural analgesia.

Data were analyzed by use of paired or unpaired *t* test and by calculating Pearson correlation coefficients with the Systat statistical program (Systat, Inc.) on a Dec Rainbow computer.

Results

In this investigation, cardiac output increased in every patient during prostaglandin E_2 induction. The average preinduction cardiac output was 7.8 ± 2.2 L /min (mean ± SD). These values did not differ statistically from cardiac output measured with the same

*P < 0.05 compared with preinduction values.

technique, as part of another study, in 17 women between 17 to 23 weeks' gestation ($p > 0.01$).[11]

The maximum cardiac output achieved during induction was 13.3 ± 5.6 L/min. The average increase in cardiac output was 5.5 L/min, or 64.5% above preinduction values. There was considerable variation among patients. The increase in cardiac output was accompanied by an increase in both heart rate and stroke volume. Preinduction cardiac output, cardiac index, heart rate, and stroke volume increased significantly during treatment ($p < 0.01$) (Table II).

The time that peak cardiac output is sustained is important. However, this is difficult to describe or quantitate because of the variable length for inductions. Generally, cardiac output increased soon after prostaglandin E_2 induction began. Cardiac output continued to increase during induction with peak values obtained just before delivery. Representative cardiac output responses are depicted in Fig. 1.

The change in cardiac output was not related to length of gestation, parity, duration of induction, or total dose of prostaglandin E_2 (Table I). However, patients with higher preinduction cardiac output showed a significantly greater increase during induction ($r = 0.684$, $p < 0.05$). The mean cardiac output was not statistically different in cases of abortion for fetal death in utero compared to those for other indications.

No cardiovascular morbidity occurred among patients in this study.

Comment

The percent increase in cardiac output found in this study is similar to that described for labor at term.[12] However, the absolute cardiac output in L/min is greater because cardiac output is higher during midpregnancy than at term.[3] Cardiac output has been reported to rise 2.5 L/min during the second stage of labor at term.[7] In the present study the cardiac output increased by an average of 5.5 L/min. The magnitude of cardiac output increase during prostaglandin E_2 termination would appear to be of clinical significance in patients with known cardiovascular disease or limited cardiac reserve.

In the classic studies on cardiac output of Uelanc and Hansen[13] which used a dye dilution technique, they reported a range of 3.3 to 13.0 L/min/hr for women at term before induction of labor. Our preinduction values showed less range (4.2 to 10.9 L/min/hr). However, during active labor we did see a considerable variation among patients. This could reflect individual patient response to labor, prostaglandin, hormonal milieu associated with fetal death, administered analgesics and/or response to pain.

Narcotic analgesics and sedatives have no consistent affect on cardiac output.[7] During labor, response to pain can increase cardiac output.[12] However, it would be unethical to perform an abortion without providing adequate analgesics consistent with each patient's request. We feel that the analgesics used reflect the clinical situation under which abortion is performed.

It is beyond the scope of this study to determine whether prostaglandin E_2 has a direct effect on the maternal cardiovascular system contributing to the significant increase in cardiac output observed. There is some information that suggests this possibility, since in nonpregnant individuals, prostaglandin E_2 is a known potent vasodilator resulting in a lowering of blood pressure, increase in heart rate, and cardiac output.[14]

Although the mean cardiac output increase was less among patients undergoing pregnancy termination for fetal death in utero (3.6 ± 2.6 L/min) versus viable fetus (6.0 ± 3.6 L/min), statistical significance was not reached ($p = 0.2376$). This may reflect the small number of patients with intrauterine fetal death and the wide range of cardiac output response. Further study would be needed to resolve this issue.

Whether other methods used to induce labor for second-trimester abortion cause similar increases in cardiac output is unknown. We studied one patient, not included in this investigation, who underwent abortion by use of intra-amniotic urea. Cardiac output increased 2.8 L/min, or 50% above preinduction values.

With patients known or suspected to have cardiovascular disease, the increase of cardiac output that occurs during induction of labor for second-trimester abortion should be considered. Surgical dilatation and evacuation could be considered, since this method may impose less cardiovascular alterations.

Prostaglandin E_2 release on the fetal and maternal sides of the amnion and chorion-decidua before and after term labor

John A. McCoshen, Ph.D., Kimberly A. Johnson, B.Sc., Norman H. Dubin, Ph.D., and Ramesh B. Ghodgaonkar, B.Pharm.

Winnipeg, Manitoba, Canada, and Baltimore, Maryland

Release of prostaglandin E_2 on each of the fetal and maternal sides of the fetal membranes (8 cm^2) from term cesarean (no labor) and spontaneous vaginal (labor) deliveries was studied with the use of dual-compartment perfusion chambers. Postlabor amnion released significantly ($p < 0.05$) more total prostaglandin E_2 (5.66 ± 1.02 ng, mean ± SEM) than prelabor tissue (3.34 ± 1.76 ng) with equivalent prostaglandin E_2 levels being released on both sides. A net decrease ($p < 0.001$) in prostaglandin E_2 release by chorion-decidua was identified after labor (fetal = 0.12 ± 0.05 ng; maternal = 0.17 ± 0.09 ng) when compared with that before labor (fetal = 1.28 ± 0.69 ng; maternal = 2.31 ± 0.56 ng). Amnion-chorion-decidua released more prostaglandin E_2 on the fetal side after labor (2.37 ± 1.43 ng) than prior to labor (1.49 ± 0.60 ng); however, prostaglandin E_2 on the maternal side was significantly less ($p < 0.05$) after labor (0.24 ± 0.12 ng) when compared with that of the prelabor membrane (2.03 ± 1.08 ng). Elution of prostaglandin E_2 from preincubated membranes anc endogenous membrane prostaglandin E_2 content showed similar results. Thus concentrations of prostaglandin E_2 on the maternal side of the fetal membranes appear diminished after spontaneous labor despite an increased release from the fetal surface. (Am J Obstet Gynecol 1987;156:173-8.)

Production of prostaglandins by fetal membranes, including amnion and chorion, as well as accumulated prostaglandins in the amniotic fluid may be associated with the initiation and/or maintenance of human labor. Cervical dilatation and induction of labor occur after cervical exposure to or infusion of amniotic fluid with prostaglandin E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$).[1, 2] Proposed sources of amniotic fluid prostaglandins include the fetal membranes and fetal kidney since PGE_2 and $PGF_{2\alpha}$

Table I. Release of PGE_2 by term fetal membranes

Membrane type*	Net PGE_2 (ng) (mean ± SEM)	
	No labor (cesarean section)	*Labor (vaginal delivery)*
Amnion	3.49 ± 0.81	7.04 ± 1.91
Chorion-decidua	2.00 ± 0.69	0.76 ± 0.27
Amnion-chorion with decidua	2.38 ± 0.45	1.75 ± 0.53
Amnion/chorion-decidua†	1.85 ± 0.50	—

*n = 8 for each value.

†Amnion separated from chorion-decidua and then replaced.

production by amniotic cells and concentrations in fetal urine increase significantly between the onset of labor and parturition.[3-6] Furthermore, both placenta and decidualized endometrium are production sites of prostaglandins.[7,8] The findings of increased fetal membrane production and amniotic fluid concentrations of prostaglandins have led to speculation that the availability of prostanoid hormones to the myometrium increases about the time of onset of labor.[9] Thus the amount of prostaglandin released on the maternal side of the gestational sac would necessarily increase with the onset of labor.

The present study tested the hypothesis that during the course of labor PGE_2 release by fetal membranes favors an increased availability of this prostaglandin to the myometrium. Furthermore, the effect of membrane dissociation of amnion from chorion-decidua on the release of PGE_2 was also tested since alterations in membrane transport and physiologic properties occur under those conditions.[10] To facilitate this study PGE_2 release was equated to a constant surface area of fetal membrane maintained in dual-compartment perfusion chamber systems designed to simulate in vivo conditions.

Material and methods

Reflected fetal membranes consisting of amnion, chorion-decidua, amnion-chorion with adherent decidua, and amnion mechanically separated from chorion-decidua and subsequently replaced in contact were used in these experiments. The membranes were obtained from four normal repeat term cesarean sections, without labor, between 38 and 39 weeks' gestation, and from four normal pregnancies delivered vaginally after spontaneous labor and parturition between 39 and 41 weeks' gestation. From each afterbirth the reflected membranes were cut free distal to the placenta and washed in cold phosphate-buffered saline, at pH 7.4, to remove residual blood. Disks (8 cm^2) of either amnion, chorion-decidua, amnion-chorion with adherent decidua, or, in the case of cesarean deliveries, amnion separated from chorion-decidua and then replaced were cut and mounted onto circular 22-mesh stainless steel screens as described previously.[10] Respective membrane types from each pregnancy were prepared in duplicate and mounted in dual-compartment perfusion chambers, such that each hemichamber enclosed either the fetal or the maternal membrane side. The membranes were checked for leakage first by addition of 9 ml of synthetic amniotic fluid at pH 7.4 to the fetal chamber and observation of the maternal chamber for 10 minutes. The synthetic amniotic fluid was used as an incubation medium because of its superior qualities in maintaining membrane viability and metabolism in vitro.[11] After confirmation of a leak-free preparation, the maternal chamber was filled to 9 ml with synthetic amniotic fluid. The membranes were preincubated for 2 hours at room temperature (20° C) with a change of synthetic amniotic fluid at 1 and 2 hours, respectively. After each time period, a 0.5 ml sample of synthetic amniotic fluid was removed from each hemichamber, pooled, and quick-frozen in acetone–dry ice (−70° C). After preincubation the chambers were placed in a water bath at 37° C and the temperature of the perfusion chambers was allowed to equilibrate for 15 minutes.

After equilibration a 0.5 ml aliquot of fluid was removed from each hemichamber at 0 hours and again at 2 and 4 hours. During incubation, chamber fluids were aerated with a continuous circulation of humidified filtered air delivered via a 22-gauge needle. After sampling, the chamber fluids were replenished with synthetic amniotic fluid to maintain a constant volume of 9 ml on each side.

At the end of each experiment all membranes were blotted, weighed, and fixed in neutral buffered formalin for histologic evaluation of viability. Paraffin sections were stained with 1% toluidine blue.

Reflected samples of chorion-decidua from an additional five cesarean deliveries and five vaginal deliveries were each homogenized in 1:1 (w/v) synthetic amniotic fluid, pooled, and centrifuged at 5000 × g for 30 minutes at 4° C. The supernatants were collected and again centrifuged for 30 minutes. Supernatants were then diluted 1:8 in synthetic amniotic fluid and evaluated for PGE_2 content in each of the cesarean and vaginal chorion-decidua pools.

Radioimmunoassay of PGE_2 was performed according to the method of Dubin et al.[12] with the use of rabbit anti-PGE_2 antibody produced by antigen coupling to bovine serum albumin. Samples of synthetic amniotic fluid containing antisera were incubated overnight at

Table II. Results of statistical analysis

Type of membrane	Mode of delivery		Membrane side			
			No labor (cesarean section)		Labor (vaginal delivery)	
	F value*	p†	F value	p	F value	p
Amnion	4.29	<0.05	0.18	NS	0.24	NS

Amnion-chorion with decidua	2.64	NS	0.28	NS	4.22	<0.05
Amnion/chorion-decidua‡	—	—	9.02	<0.01	—	—

Summary of multiple analysis of variance of term fetal membrane PGE_2 released during a period of time according to mode of delivery (cesarean section without labor versus spontaneous labor and vaginal delivery) and membrane side (fetal versus maternal).

*F Values at 1 to 48 degrees of freedom.

†Probability: NS = Not significant.

‡Amnion separated from chorion-decidua and then replaced.

4° C along with the appropriate tracer. Separation of bound from free antigen was accomplished with dextran-coated charcoal. The limit of detection of PGE_2 was 12 pg/ml with intra-assay and interassay coefficients of variation of <10% and 15%, respectively. PGE_2 values from membrane incubates were converted to total PGE_2 released on each of the fetal and maternal sides; that is, radioimmunoassay PGE_2 values in picograms per milliliter × 9 ml of medium on each side equals PGE_2 released by 8 cm^2 of membrane into the fetal or maternal hemichamber. Thus the results reflect total PGE_2 release by a standard membrane surface area common to each experiment. All radioimmunoassay results were analyzed by multiple analysis of variance to test the treatment effects of type of membrane, membrane side, mode of delivery, and incubation time. Multiple two-tailed *t* tests and analysis of correlation were also used for testing specific variables.

Results

During preincubation at 20° C, PGE_2 eluted from all membrane types (Table I) with the highest levels originating from amnion obtained from vaginal deliveries. The lowest concentrations of PGE_2 were eluted from chorion-decidua from vaginal deliveries. The profiles of PGE_2 release in nanograms per hemichamber during 4 hours of incubation at 37° C for each membrane type from the two modes of delivery are presented in Figs. 1 to 4. Statistical analysis identified significant differences in PGE_2 release by the various membrane types, according to side and mode of delivery (Table II). In the case of amnion, significantly higher PGE_2 levels were released during a period of time by vaginal membranes than by cesarean membranes (Fig. 1) whereas chorion-decidua obtained from vaginal deliveries failed to produce a net increase in PGE_2 during a period of time when compared with membranes obtained from cesarean sections (Fig. 2). The amnion-chorion with adherent decidua from both cesarean and vaginal deliveries released substantial PGE_2 (Fig. 3); however, significant differences in total PGE_2 were identified relative to the membrane side only. Membranes from cesarean deliveries consisting of dissociated amnion and chorion-decidua produced a net accumulation of PGE_2 during a period of time but the concentration profiles relative to side differed significantly from those of intact amnion-chorion with adherent decidua also derived from cesarean deliveries (Fig. 4). Thus mechanical disruption of cellular contact between amnion and chorion-decidua obtained from cesarean deliveries resulted in a reduction of PGE_2 release into the maternal hemichamber. PGE_2 on the fetal or amniotic side, however, remained equivalent to that of the fetal sides of both isolated amnion membranes and amnion-chorion with adherent decidua membranes from cesarean deliveries. Histologic assessment of each type of membrane failed to identify changes in membrane viability subsequent to incubation when compared with sections of fresh specimens. Pooled extracts of chorion-decidua from cesarean deliveries contained the equivalent of 6.5 ng of PGE_2 per gram of tissue whereas endogenous PGE_2 from chorion-decidua obtained after spontaneous labor and vaginal delivery was almost fourfold less, at 1.8 ng/gm of tissue.

Comment

A net increase in prostaglandin production by amniotic cells derived from term pregnancy without labor compared with pregnancy terminating with spontaneous labor and parturition has been described previously.[7, 8, 13] Studies on the production of various prostaglandins by chorionic and decidual tissues, in addition to amnion, have led to speculation that the fetal membranes may be involved in the initiation and maintenance of labor.[8, 13] Furthermore, intra-amniotic injection of prostaglandins is known to induce labor in a

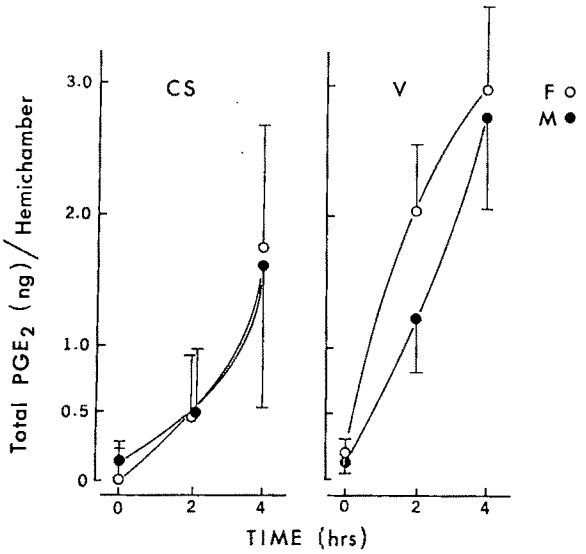

Fig. 1. PGE_2 release during 4 hours by 8 cm^2 disks of amnion derived from cesarean *(CS)* and vaginal *(V)* deliveries. Total PGE_2 release by *V* amnion was significantly greater than that by *CS* amnion; however, no significant difference between fetal *(F)* and maternal *(M)* PGE_2 concentrations exists within each of *CS* or *V* delivered membranes.

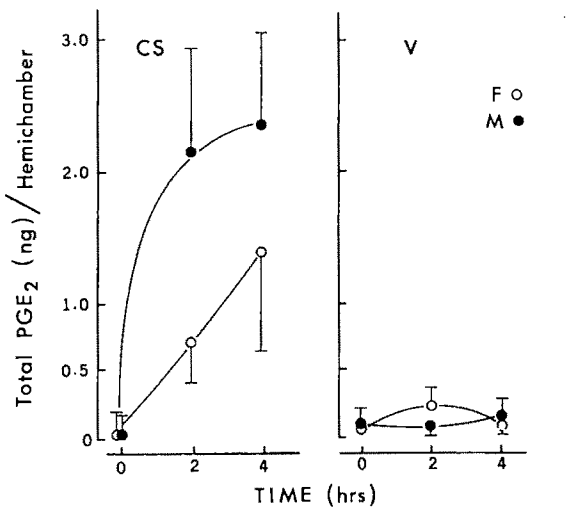

Fig. 2. Profiles of PGE_2 release during 4 hours by chorion-decidua of 8 cm^2 surface area from cesarean section *(CS)* and vaginal *(V)* deliveries. A significant difference ($p < 0.001$) exists in total PGE_2 release by *CS* versus *V* delivered membranes that is associated with decreased PGE_2 concentrations on the fetal *(F)* and maternal *(M)* sides of *V* delivered membranes.

number of circumstances.[2] Presumably, prostaglandin injection simulates the condition of increased amniotic fluid prostaglandin concentrations associated with term gestation.

The present study suggests that the known increase in amniotic fluid PGE_2 concentration occurring between the onset of labor and parturition may result in large part from increased amniotic productivity of

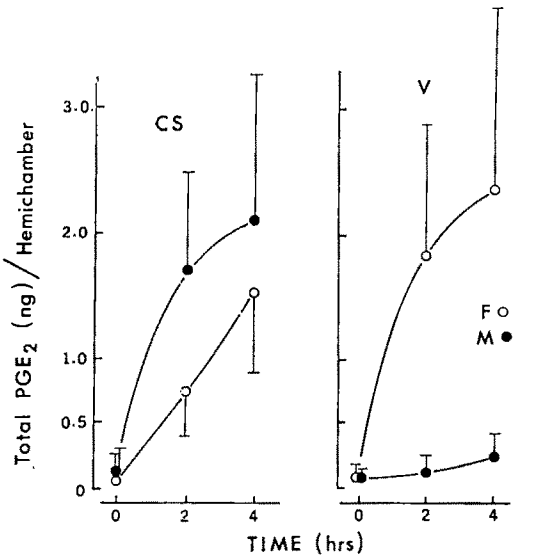

Fig. 3. PGE_2 release during 4 hours by composite 8 cm^2 disk of intact membranes consisting of amnion retained in cellula contact with chorion-decidua. PGE_2 increases on the fetal *(F* side of vaginal *(V)* delivered membranes were similar to thos of amnion, whereas PGE_2 on the maternal *(M)* side declinec to levels similar to those of chorion-decidua membranes fron cesarean section *(CS)* deliveries.

PGE_2 during that time. The finding of equivalent con centrations of PGE_2 on fetal and maternal sides of th amnion implies that amniotic PGE_2 becomes accessibl to the underlying chorion and possibly available fo transport by chorion-decidua to the myometrium However, the data on directional output of PGE_2 afte vaginal delivery by intact amnion-chorion with adher ent decidua, while reaffirming an increase in PGE_2 or the amniotic or fetal side, clearly display a substantia decline in net PGE_2 available to the maternal sid of the membranes. It is possible that the chorionic decidual component of amnion-chorion with adheren decidua from vaginal delivery possesses either a lo capacity for PGE_2 production and/or release or an al teration in ability to rapidly metabolize amniotic PGE_2 during transport. Chorion-decidua from vaginal deliv ery displayed almost no net PGE_2 release during a pe riod of time, unlike chorion-decidua from cesarean de liveries. Whatever functional mechanism(s) exists to ac count for this observation, it is apparent that unde these experimental conditions the availability of PGE_2 to the maternal or myometrial side is substantially re duced after spontaneous labor and delivery. Thus these results are contrary to the concept that PGE_2 produc tion by reflected fetal membranes avails increasing con centrations of the prostaglandin to the myometrium Additional evidence in support of this view was iden tified where endogenous PGE_2 content of chorion decidua from vaginal deliveries was almost fourfold les than that of tissue from cesarean delivery, suggestin

a net decline in PGE_2 on the maternal side of the membranes sometime during labor. Similarily, elution of PGE_2 from chorion-decidua during preincubation was approximately threefold less by vaginal delivery tissue than by cesarean delivery tissue.

It is possible that these results reflect a short-term decline in membrane PGE_2 production or the availability of membrane prostaglandin precursors, such as arachidonic acid,[13, 14] subsequent to or during parturition. However, this may not be the case since amniotic PGE_2 release increased at a time coincident to a decrease in chorionic-decidual PGE_2 concentrations. Also composite amnion-chorion with adherent decidua membranes from vaginal deliveries display differential PGE_2 release similar to that on the fetal and maternal sides of isolated amnion and chorion-decidua, respectively. Alternatively, the decidual component of chorion-decidua may rapidly convert PGE_2, produced by amnion and chorion, to $PGF_{2\alpha}$. Therefore, PGE_2 levels on the fetal side of isolated chorion-decidua would be expected to remain high, but this was not the case.

In those experiments where amnion and chorion-decidua were separated and subsequently replaced in contact, PGE_2 release by amnion without chorion-decidua from cesarean deliveries more closely resembled that of intact amnion-chorion with adherent decidua from membranes delivered vaginally than intact amnion-chorion with adherent decidua from cesarean deliveries. This unusual finding may suggest that the trauma of labor influences chorionic-decidual PGE_2 release or that an interaction between the fetal membranes exists relative to the regulation of PGE_2 production. Alterations in fetal membrane transport properties have been observed under similar experimental conditions in that decidual prolactin transport ceases after dissociation of amnion from chorion-decidua.[10]

In summary, the hypothesis of this study, that the availability of fetal membrane PGE_2 to the maternal or myometrial surface increases from a time before the onset of labor until parturition, must be rejected. The results suggest that endogenous chorionic-decidual content and release of PGE_2 decrease significantly sometime during labor. The possibility that this change is acute, occurring during parturition, cannot be excluded; however, amniotic PGE_2 release was substantially increased after parturition. Thus the availability of chorionic-decidual PGE_2 to the myometrium may indeed decline during labor, suggesting that differential metabolic changes occur in the fetal membranes during this time. Possibly chorionic-decidual PGE_2 is rapidly converted to some other metabolite. Finally, membrane trauma resulting from labor may account in part for the alteration in chorionic-decidual PGE_2 release since spontaneous membrane rupture and amniotomy,[15] amniotic sac distention,[16] and chorioamnionitis[17] are associated with the initiation of labor.

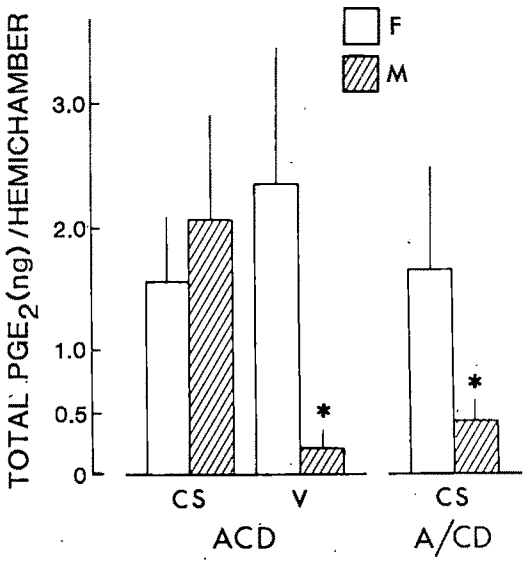

Fig. 4. Comparison of net 4 hour release of PGE_2 by composite 8 cm^2 disks of amnion-chorion membranes with adherent decidua *(ACD)* from cesarean section *(CS)* and vaginal *(V)* deliveries and dissociated disks *(A/CD)* of membranes from *CS* deliveries. Although *A/CD* membranes came from cesarean sections, PGE_2 production was more similar to that of *ACD* from *V* deliveries than from *CS* deliveries. A significant difference exists in PGE_2 concentrations on the maternal *(M)* side versus the fetal *(F)* side of *ACD* from *V* deliveries ($p < 0.05$) and *A/CD* from *CS* deliveries ($p < 0.01$).

Thus, considering the numerous variables involved in the physiology of labor, membrane trauma may warrant further attention for study. However, some other event(s) is then required to initiate the process of labor, leaving the uterus, placenta, and fetus as possible sites of pertinent activity.

A prospective study to compare serum human placental lactogen and menstrual dates for determining gestational age

Paul G. Whittaker, D.Phil., Tom Lind, M.B., B.S., and Jacqueline Y. Lawson, B.Sc.
Newcastle upon Tyne, England

In a group of 575 healthy pregnant women with certain menstrual dates the estimation of the length of gestation from maternal serum human placental lactogen concentrations has been compared with gestational age calculated from the last menstrual period and ultrasonic measurements of the fetal biparietal diameter. In 412 of these patients labor started spontaneously, and the estimated dates of delivery determined by these three methods were also compared. In the range of 9 to 17 weeks of pregnancy, gestational age can be determined by human placental lactogen measurement to within 7 days (±1 SD) which compares favorably with other methods. Regarding the prediction of the expected date of delivery, 88% were delivered within 2 weeks of the date predicted by last menstrual period, 82% within 2 weeks of the sonar date, and 80% by the date determined by human placental lactogen assessment. Prediction of delivery in a further group of 139 women with uncertain dates gave 73% within 2 weeks by sonar date and 69% within 2 weeks by human placental lactogen determination. We suggest human placental lactogen measurements should become part of routine antenatal care complementing rather than replacing the role of ultrasonic scanning. For those doctors and patients who wish to avoid more exposure to ultrasonic scanning than absolutely necessary, human placental lactogen estimates offer an alternative method for assessing the length of gestation. (Am J Obstet Gynecol 1987;156:178-82.)

Key words: Gestational age, human placental lactogen, ultrasound

One of the major facts the obstetrician needs for the management of a pregnancy is an accurate knowledge of the length of gestation. Traditionally this is calculated from the first day of the last menstrual period, and for women in whom this date is known with certainty and whose cycles are regular, such calculations are reasonably precise.[1, 2] Unfortunately some women are unable to remember accurately the date of their last menstrual period, others have irregular menstrual cycles, and for some patients the date offered represents withdrawal bleeding after discontinuation of the use of oral contraceptive agents, making its relation to ovulation less predictable; in such circumstances alternative methods for determining the duration of pregnancy must be used. Ultrasonic measurements of various fetal parameters such as the crown-rump length,

Lower limit of hPL prediction (days)	0.007-63	—
Upper limit of hPL prediction (days)	0.85-122	—

the biparietal diameter, or the length of the femur have proved to be useful but their relation to gestational age is dependent on the stage of pregnancy at which such measurements are made[3] and the skill and experience of the operator. In addition the equipment is expensive to buy and maintain, and patients may have to travel long distances to reach such facilities.

The pregnancy-specific hormone human placental lactogen is detectable in maternal blood soon after implantation and increases some 300-fold in concentration during the first trimester.[4] In a preliminary study we reported that concentrations of human placental lactogen between 0.01 and 0.8 μU/ml could be used to determine gestational age to within 6.3 days (SD); these concentrations approximate for the first trimester.[5] The assay has since been introduced as a routine clinical service for all patients booking at this hospital; since it is the practice of offer ultrasonic scanning to every patient at about 16 to 18 weeks of pregnancy, we have been able to compare estimates of gestational age from human placental lactogen measurements both with those calculated from the last menstrual period and by ultrasonic measurements of the biparietal diameter.

Patients and methods

Assays of human placental lactogen were undertaken on 886 consecutively booked patients, of whom 49 (5.5%) spontaneously aborted, 19 (2.1%) were delivered elsewhere, and 31 (3.5%) had human placental lactogen concentrations at booking outside of our working range. Nine patients had twin pregnancies, and their data have been analyzed separately, leaving 778 patients who, while displaying the usual spectrum of obstetric outcomes, either had a live birth or were delivered after 28 completed weeks. In this group 585 (75.2%) mothers had reliable menstrual data and 193 did not.

Radioimmunoassay. The assay was based on materials supplied by RIA (UK) Ltd. (Washington, Tyne and Wear, England) as its "hPL early gestational age" kit. The standards were prepared from the World Health Organization standard 73/545 (1 mU = 1 mg) and ranged from 0.007 to 0.85 mU/L; normal male serum was added to standards to counteract nonspecific serum effects. Standards and undiluted samples were incubated with antiserum and iodinated human placental lactogen for 30 minutes at room temperature. A mixture of polyethylene glycol and preprecipitated second antibody was then added, and after a further 15 minutes the samples were processed and counted. Within-assay variation was 2.1% at 0.132 mU/L (n = 10) and across-assay variation was 7.6% at 0.167 mU/L (n = 22).

Sonar scanning. The machine used was a GL Diasonograph NE4200 modified for use with a real-time 3.5mHz head and a 4-bit and 6-bit digital scan converter.

Statistics. Statistical tests for comparison of groups and analysis of linear regression were as described by Armitage.[6]

Results

Reliable dates: human placental lactogen findings

Index group: Initially very strict patient criteria were defined for the creation of an index group in which the relation of serum human placental lactogen to gestational age (in days) could be determined. Each woman had to be able to provide a written record of her last menstrual period, to have a cycle length not exceeding 44 days,[7] to have a sonar assessment of gestational age from the fetal biparietal diameter within 12 days (that is, ±2 SD) of that calculated from the last menstrual period, and finally to have a live, healthy baby following the spontaneous onset of labor at term (defined as 37 to 41 completed weeks).[8] With use of the present kit the range for serum human placental lactogen was optimized at 0.007 to 0.85 mU/L so that the woman also had to have values within this range. There were 139 patients who fulfilled all of these criteria, and linear regression analysis of their data showed that gestational length could be calculated to within 7 days (1 SD) of the last menstrual period date; the earliest estimate of gestation possible was 63 days, with an upper limit of

Table II. Estimation of gestation length from maternal serum human placental lactogen concentrations (585 patients) and ultrasonic measurements of the fetal biparietal diameter (575 patients), relative to that determined from the last menstrual date*

Distribution (days)	*Human placental lactogen (%)*		*Sonar (%)*	
≤6	63	91	63	90
7-13	28		27	
14-20	6		9	
21-27	3		1	
≥28	0.3		0.4	

*Differences in human placental lactogen dates versus differences in sonar dates: $r = 0.5$ ($p < 0.001$). Mean difference (calculated from last menstrual dates): human placental lactogen, 0.3 ± 8.4 (NS); sonar, -4.6 ± 6.6 ($p < 0.001$). The negative bias in the sonar dating occurred because the regression line used applied to the whole range of pregnancy and was not optimized to gestation limited to 17 to 19 weeks.

122 days. The details of the analyses are shown in Table I.

Reliable dates group: The index group was now widened to include those who had reliable menstrual dates, a cycle length not exceeding 44 days, a serum human placental lactogen concentration inside the working range, and in whom the outcome was anything other than spontaneous abortion or twins. The sonar findings were not taken into account. This increased the group to 585 (19 women had been excluded because their human placental lactogen values were outside the working range). The mean gestation at booking for the group as a whole was 12 weeks (±2 weeks; 1 SD), ranging from 6 to 19 weeks. The linear regression calculated for this group did not differ significantly from that of the index group (Table I). Use of a log transformation of human placental lactogen values made the fit somewhat worse ($r = 0.744$) and using a quadratic function gave only a marginal improvement ($r = 0.781$). It was thus decided to use the regression line determined from the index group for all further comparisons.

One way of comparing how well human placental lactogen assessment performs in a group of individuals is to subtract the length of gestation calculated by means of the last menstrual period from the length of gestation determined by human placental lactogen. There will be some underestimates and some overestimates, but with a large group the mean of all of the differences should not be significantly different from zero and should have a small standard deviation. This proved to be the case for the 585 women with reliable menstrual dates; the mean diference was 0.3 days, with a standard deviation of 8.4 days. The distribution of gestational estimates by human placental lactogen was such that 91% were within 13 days of their last menstrual period date (Table II). Calculations of gestational age from measurements of human placental lactogen at the extremes of the assay range did not reveal any systematic bias.

Table III. Estimation of expected date of delivery in 412 spontaneous deliveries with *reliable* menstrual dates

Reliable dates: ultrasonic findings

Of the 585 women in whom human placental lactogen data were available, 575 also had ultrasonic measurements of the biparietal diameter. Unlike the human placental lactogen determinations the ultrasonic measurements could not be undertaken blind because the operators knew the patients had deliberately been asked to come at 16 to 18 weeks' gestation; indeed the mean gestation from last menstrual period at scanning for the whole group was 17.5 weeks, and 72% were seen within 2 weeks of the mean. Use of the difference between the ultrasonically determined length of gestation and that derived from the last menstrual period showed that 90% of the mothers were within 2 weeks of the gestation calculated from the menstrual date (Table II).

For the estimation of date of delivery the measurements of 412 patients who had certain last menstrual period dates as well as both human placental lactogen and ultrasonic data and who went into spontaneous labor (mean, 278 days' gestation) were analyzed. Calculated from the last menstrual period the percent of patients delivered within 2 weeks of the expected date of delivery was 88%, from sonar determinations it was 82%, and from human placental lactogen determinations it was 80%. The distributions are given in Table III.

Uncertain dates. A further patient group was com-

posed of 220 women for whom there was reason to doubt the accuracy of their menstrual dates. In 124 cases the mothers could not remember their dates, a further 83 said the date they gave represented withdrawal bleeding from oral contraception, and 13 women had such irregular cycles their date was an unreliable index to ovulation. In this group 146 women experienced spontaneous onset of labor after uncomplicated pregnancies and delivered live healthy babies; of these, 139 (95%) had human placental lactogen values within our working range. We compared their expected date of delivery determined both from human placental lactogen concentrations and from sonar results with the actual date of delivery; 69% were delivered within 2 weeks of the dates predicted by human placental lactogen, and 73% were delivered within 2 weeks of the date predicted by ultrasonic scanning (Table IV).

Twins. There were nine pairs of twins in the series and the human placental lactogen/last menstrual period gestation differences in this group averaged 8 days (±14 days; 1 SD). The numbers are too few to draw conclusions, but the apparent trend to overestimate gestation is probably a function of the small number in this group.

Spontaneous abortions. There were 39 women who spontaneously aborted and the mean gestational difference in this group was −5.3 (±14.3; 1 SD) days, which just achieved significance ($p < 0.05$). This could have been anticipated from the endocrine changes known to occur before spontaneous abortion.

Comment

It has been suggested that the maternal serum concentrations of human placental lactogen, human chorionic gonadotropin and Schwangerschaft's protein can be used to determine the length of pregnancy during the first and second trimesters of pregnancy. The use of human chorionic gonadotropin appears to be reliable,[9] but its clinical usefulness is limited to <10 weeks because after this time maternal serum levels decline. Both human placental lactogen and Schwangerschaft's protein increase steadily throughout pregnancy[10] and appear to give clinically useful estimates of the length of gestation during the first and second trimesters,[5, 11, 12] but these studies involved relatively small numbers of patients. In this investigation a large number of patients have been studied, embracing the usual range of obstetric outcomes and the human placental lactogen estimates of the length of pregnancy compared not only to last menstrual period data but to sonar estimates of gestation and the actual date of delivery in those women undergoing spontaneous labor.

Our original series had been composed of women attending our research unit who had usually attended the antenatal clinic before 10 weeks' gestation.[5] The present large population attended for the first time over a much wider range of pregnancy, but 97% of those with certain menstrual dates had human placental lactogen values within our original range.[5] A new regression line was calculated from the present index group because of the change from an in-house human placental lactogen assay to a commercial kit; the standard deviation was 7 days and, when applied to everyone with reliable dates, placed 91% within 2 weeks of their last menstrual period date. Our routine clinical ultrasonic service for the same group yielded a standard deviation of 6 days and placed 90% within 2 weeks of the last menstrual period dates. It must be borne in mind that the sonar measurements were made with full knowledge that the patients were approximately 16 to 18 weeks pregnant whereas the human placental lactogen determinations were blind and made over a much wider range of weeks.

It has been suggested that one way of checking the accuracy of gestational assessment would be to compare the actual date of confinement against that predicted by any particular assessment technique. Campbell et al.[13] reported that 89% of patients delivered within 2 weeks of the ultrasonically predicted date of delivery, whereas in the same group only 85% delivered within 2 weeks of the last menstrual period predicted date. Ahmed and Klopper[12] used a similar argument. In our series of the 412 women with reliable dates who went into spontaneous labor, 88% were delivered within 2 weeks of the date predicted by last menstrual period (that is, the date of onset of the last menstrual period plus 280 days), 82% within 2 weeks of the ultrasonic date, and 80% by the date derived by human placental lactogen. While it is of interest that data from different sources are so similar, we feel this form of analysis to have little clinical relevance; many factors influence the time at which an individual woman will go into spontaneous labor, and 280 days is not a rigid interval. The work of Guerrero and Florez[1] showed that the interval from ovulation to spontaneous delivery had a standard deviation of 12 days.

A group of patients of particular clinical concern are those with uncertain dates: 25% in our study. Of these, 95% had serum human placental lactogen levels within our range when they first attended the antenatal clinic, and all had a sonar estimation of biparietal diameter. Estimation of date of delivery in these women was similar for both methods, some 70% delivering within 2 weeks of the predicted expected date of delivery.

In our experience dating the length of gestation by human placental lactogen levels and the sonar estimate of the biparietal diameter are equally reliable. It could be argued that use of sonar determinations of the fetal

crown-rump length would allow a more precise assessment of gestational length, but this was not the experience in our previous though smaller series.[5] The standard deviation of the crown-rump length/last menstrual period gestational determinations was ±6.1 days which was not significantly different from the ±6.6 days reported here for biparietal diameter estimates. This is not to suggest that the estimation of human placental lactogen should replace sonar determinations but that both methods have a role to fulfill. Pregnant women have blood sampled at their first antenatal visit for a variety of tests so the cost of taking the blood sample for human placental lactogen in terms of syringes, needles, and the manpower required is shared across this range of tests. Since the hormone is stable in serum at room temperature, the sample could be sent to a central laboratory from a wide area and a technician could process hundreds of samples per week. Finally, immunoassay equipment is available in many laboratories and their capital cost is spread over the many hormone assays requested by doctors in different disciplines. Ultrasonic machines used for obstetric scanning are often dedicated to that purpose, are expensive to buy and maintain, and require highly experienced staff to use them and interpret the findings; moreover, the patients usually have to travel to the facility. For those hospitals performing a sonar scan at booking for gestational assessment and repeating the scan at about 18 weeks for fetal anomaly detection, the estimate of human placental lactogen could offer a reliable and cheaper alternative to the first scan. It would also offer flexible clinical management: Every patient could be offered an human placental lactogen assessment at booking, and for those in whom there was a discrepancy between the last menstrual period and human placental lactogen estimates, a sonar scan could be arranged.

Why use assay methods at all if the sonar method is reliable? Some reasons have been discussed above, but a major reason is the 20% or so of women who have no menstrual date to offer. In such circumstances rather than the sonar estimate being used alone for dating, a second diagnostic system is now available. There are also circumstances in which women with apparently reliable menstrual dates have a sonar-derived gestational age at variance with these dates; an independent human placental lactogen assessment would obviously be useful in such circumstances. Finally, for those places that do not have ready access to a sonar service, human placental lactogen assay could offer a cheap centralized facility for assessing gestational age. For these reasons we suggest human placental lactogen measurements should become part of routine antenatal care, complementing rather than replacing the role of ultrasonic scanning.

We are grateful to RIA (UK) Ltd., Washington, England, for its contribution toward this project. The assistance of Jean Gerrard, Thelma Scholefield, and Mary Maxwell with data collection and analysis is also appreciated.

Similarities of Negro and Caucasian fetal extremity lengths in the interval from 9 to 20 weeks of pregnancy

Robert A. Munsick, M.D., Ph.D.
Indianapolis, Indiana

Foot, leg, and arm measurements were compared from 599 electively aborted fetuses of Negro and Caucasian women who had reliable menstrual dates and agreement between dates and uterine size. When compared by week, no significant racial differences were detected in the means of any of these measurements between 9 and 20 menstrual weeks of pregnancy. The combined, corrected data provided smoother curves than those previously published. The following formulas are recommended for weeks 9 to 20 of pregnancy, where W = weeks and F, L, and A are the foot, leg, and arm measurements in centimeters: $W = 4.5261 + 11.937(F) - 4.4895(F^2) + 0.71583(F^3)$; $W = 5.9957 + 5.7279(L) - 1.2246(L^2) + 0.11880(L^3)$; $W = 5.4007 + 5.0305(A) - 0.93540(A^2) + 0.079022(A^3)$. (Am J Obstet Gynecol 1987;156:183-5.)

Key words: Fetus, extremity, pregnancy, race, foot, leg, arm

Recently I[1] showed that the fetal foot length data of Streeter, published in 1920, and of Hern, published in 1984, may be properly used as a "gold standard" of fetal age. However, the proportions of Negro and Caucasian mothers that underwent abortion were not known. Assuming that there were no significant racial differences, the mixed racial data were combined. (See reference 1 for additional sources.)

Jakobovits et al.[2] studied the foot and crown-rump lengths of black, white, and Central American fetuses, but because of poor menstrual dates they found it necessary to present foot lengths in terms of crown-rump lengths. They concluded that if there were racial differences in foot lengths they were probably negligible.

The purpose of this study was to determine whether there are racial differences in the foot, leg, or arm lengths of the fetuses of Negro and Caucasian mothers in the interval from 9 to 20 menstrual weeks of gestation and, if differences were not demonstrated, to improve with additional data the previously published regression equations.[1]

Material and methods

In my previous report,[1] race was not included in the data output to the computer sequential files. Therefore, the original records were compared with the mothers' charts, and when race was identified it was recorded. New cases with racial data were added to the original ones. Criteria for inclusion in the study were as follows: The mother was identified as black or white, her menstrual dates were accurate, at least one of the three fetal measurements was recorded, and the vaginal estimate of uterine size agreed within 2 weeks of dates. Measurements of the foot (heel to extended longest toe), leg (top of the flexed knee to the bottom of the calcaneus), and arm (top of the flexed elbow to the longest extended finger) were made with vernier calipers immediately after dilatation and suction or evacuation.

For simple statistical computations, such as mean, SD, and Student's *t* tests, programs were written in N-Basic for the NEC 8001-A personal computer with the use of standard formulas as previously described.[1] Polynomial regression equations for weeks, based on foot, leg, and arm lengths, were solved with the SAS statistical package of SAS Institute Inc., Box 8000, Cary, NC 27511-8000. Because most variability of dated fetal extremity measurements is thought to be caused by inconsistent times of fertilization within the menstrual cycle and poor recall of menstrual dates, ideal curves were sought by eliminating all measurements at each week that varied from the mean by more than 2 SD.

No information was obtained concerning the incidence of fetuses of mixed races. Although such pregnancies were undoubtedly included in this series, their incidence was likely well below 10%, as it is in our general obstetric populations of black and white mothers. Hence the presence of some mixed-race fetuses should not have materially influenced the results. I will therefore refer to fetal race on the basis of maternal race. Similarly, no attempt was made to define race narrowly; it was judged by the appearance of the mother. Other races were excluded.

20	3.33	3.3	3.17	3.17	5.6	5.43	5.43	6.39	6.39

S = Streeter, H = Hern, M = Munsick.[1] All measurements in centimeters.

Of the original 575 patients reported on,[1] racial data were obtained for 522. Seventy-seven new cases were introduced, bringing the total to 599.

Results

Mean extremity lengths and SDs were determined for black and white fetuses at 9 to 20 menstrual weeks. Means and variability were very similar to the values previously published.[1] With the use of Student's *t* test, no significant differences were demonstrated between any of the mean extremity measurements in white and black fetuses for any of the weeks studied (all p values >0.1; complete data are available on request).

Because significant racial differences were not demonstrated, the data were combined by week and corrected by removing all cases that departed from the combined mean by ≥2 SD. These idealized means are shown in Table I along with some of the data from Table II of my first article.[1]

With the use of these data, polynomial regression formulas were derived for foot, leg, and arm lengths. Tests of the significance of the intercepts and first through third- or fourth-order regression coefficients showed a p value of <0.002 for all third-order polynomial equations but lack of significance for all fourth-order equations. Hence third-order equations were adopted. Adjusted R^2 values for these were 0.9989 for foot, 0.9981 for leg, and 0.9992 for arm lengths. Curves of idealized fetal extremity growth with weeks of gestation are shown in Fig. 1. These are smoother than those shown in the last article.[1]

The polynomial equations to determine menstrual weeks (W) from foot (F), leg (L), and arm (A) measurements in centimeters are:

$$W = 4.5261 + 11.937(F) - 4.4895(F^2) + 0.71583(F^3)$$

$$W = 5.9957 + 5.7279(L) - 1.2246(L^2) + 0.11880(L^3)$$

$$W = 5.4007 + 5.0305(A) - 0.93540(A^2) + 0.079022(A^3)$$

Maximum errors in weeks, according to these equa-

tions and the corrected data in Table I from which they were derived, follow: for foot, −0.2 weeks at 19 weeks; for leg, +0.24 weeks at 14 weeks; and for arm, +0.2 weeks at 18 weeks. With the use of differential calculus, it was found that the greatest rates of growth, expressed in centimeters per week, were 0.39 at 16.4 weeks for foot, 0.66 at 16.1 weeks for leg, and 0.75 at 15.5 weeks for arm length.

The following naperian logarithmic formulas are acceptable but are less accurate than the polynomial formulas shown above at weeks 9, 19, and 20, especially for the leg and arm:

$$\ln(W) = [\ln(F) + 2.92247/0.434294]/2.65803$$

$$\ln(W) = [\ln(L) + 3.03217/0.434294]/2.95033$$

$$\ln(W) = [\ln(A) + 2.70467/0.434294]/2.75733$$

With the use of these logarithmic formulas, maximum errors in weeks were: for foot, +0.39 at 9 weeks and −0.59 at 20 weeks; for leg, −0.62 at 19 weeks and −1.09 at 20 weeks; and for arm, −0.71 at 19 weeks and −1.25 at 20 weeks.

Comment

The finding that race (Negro and Caucasian) does not significantly affect the fetal foot, leg, or arm length between 9 and 20 weeks adds confidence to the mixed racial data previously reported.[1] These conclusions should not be extended beyond 20 weeks or to races other than Caucasian and Negro.

For programmable calculators, the third-order polynomial equations yield quicker and apparently more accurate results than the fourth-order formulas previously presented.[1] We have found that it is frequently possible to obtain ultrasonic measurements of fetal extremities in the second and late first trimesters and that applying the above formulas to these parameters agrees very well with age estimates derived from biparietal, crown-rump, and femur measurements.

I am again indebted to Pao-Lo Yu, Ph.D., Department of Medical Genetics, Indiana University School of Medicine, for his statistical advice and review of this manuscript.

Academia—An endangered species

Douglas J. Marchant, M.D.
Boston, Massachusetts

To understand the present crisis in American medicine, it is necessary to review the relevant medical history of the nineteenth century. Only in very recent times have physicians, as a class, enjoyed a favored economic status. Medicine had been a poorly paid profession. Initially the American Medical Association waged battle against the cultists, many of whom were financially quite successful in contrast to the regular physicians. Increasing numbers of poorly educated physicians entered practice, and education reform became a major goal of the American Medical Association.

The complaint that there were too many doctors was associated with the realization that there were too few paying patients. The only patients who entered the hospitals were the indigent sick. Hospitals began as charitable institutions and until the middle of the nineteenth century served only the sick poor who needed bed care. Special institutions called dispensaries, whose origins go back to the eighteenth century, provided ambulatory care for "the deserving sick poor." As hospitals and dispensaries developed under a tradition of charitable care, the community and philanthropists provided the funds and saw to it that the institutions were run economically and efficiently. Physicians provided medical care without charge. Theoretically this was the ideal system. However, even a hundred years ago, things did not work out well. What level of poverty described the needy? For the totally destitute, there was no problem. Could the sick or poor afford to pay for medical care, and if they could, why should they not do so?

The beginnings of an adversary relationship between

the physician, the hospital, and the university began in the late nineteenth century in a nation ill equipped to deal with the social problems of the time. Dispensaries and later outpatient hospital departments accepted all comers, and many practitioners complained about the loss of patients to the dispensary.

With the decline of the dispensary, hospital outpatient departments provided comparable functions. In 1916 it was estimated that there were a total of 900 dispensaries, of which 645 were outpatient departments of hospitals.[1] According to Vietor,[2] in 1886 it was estimated that about one fourth of the population of Boston and about half the population of New York were receiving free medical treatment. In 1905 Gay[3] declared that "as a matter of public record three hundred thousand patients in Boston received practically free treatment—about half the population of the city." Obviously the practicing physician had a legitimate complaint if people who could afford private care were taking advantage of the available free care. On the other hand, some physicians viewed the dispensary as an excellent way of acquiring experience and improving their skills. The dispensaries often served as a teaching function for medical schools. Thus a free dispensary attached to a medical school might drain patients away from the private practice of the community. Dispensaries provided clinical material for the training of specialists and as a result attracted the ambitious young men who wanted training and were glad to serve in the dispensaries to get it. The dispensaries in addition maintained laboratories, and the physicians relied on "instruments of precision"—what we now call "tests." Family physicians were relatively slow in assimilating this new knowledge, and even at this early stage the differences between the services of a clinic and a private physician were obvious.

Medical advances in the latter part of the nineteenth century produced a different kind of abuse—hospital abuse, quite different from the dispensary setting. This problem had to do with patient bed care rather than ambulatory care. As I mentioned earlier, bed care in hospitals for many years was a charitable offering, and middle-class families tried to avoid this. Obviously, in addition to the stigma of a hospital admission, there was the higher death risk because of infection and other iatrogenic problems. However, because of developments in medicine, particularly the science of bacteriology and the growth of laboratory medicine, hospitals began to attract patients who could pay and therefore started to charge such patients for bed, board, and nursing services. The attending physicians, however, did not share in the subsidy. Well-to-do patients could enter the hospital, pay for their room and board and nursing, and receive excellent medical care, all without paying the attending physician. The physicians, not without reason, considered this "hospital abuse." To correct the situation, some hospitals raised no objections to the covert payment of private fees. Some physicians, especially surgeons, established their own hospitals. Many large charity hospitals established a private pavilion where staff members could take their private patients.

This process at the turn of the century marked a major transformation in medical practice. Certain aspects became more and more hospital based rather than home based. Obviously those physicians who admitted private paying patients to their service encouraged a system in which the hospital was being made directly to subserve the private interests of the individual physicians. The staff who received fees had an unfair advantage over those members of the medical community without hospital appointments—the beginnings of the "town versus gown" controversy. Doctors associated with medical schools and hospitals had privileges of hospital admission for their patients to achieve more precise diagnosis and more successful treatment. The referring physician or the family doctor was undergoing a diminution in stature. The complexities of medical education encouraged by the American Medical Association, social stratification of the community, and economic developments, all contributed to the formation of academic medicine or a medical elite.

Enter the "lodge practice." Because there continued to be too many doctors and because the younger physicians had to make a living somehow, many joined a form of prepaid health care, in which organized groups hired a physician to provide medical service to the members of that group and their families. In the east side of New York alone in 1910, it is estimated that there were 1500 to 2000 lodges. If one considers that the average income of a physician in 1910 was $2000, the young physician employed by a lodge with several hundred members would have a very good start in practice indeed.

Knapp[4] described this practice as "lowering the profession to the level of a trade," and certainly we have heard this in our day. Clearly not all physicians were opposed to this lodge practice. Some would gain a wide clinical experience much as their predecessors in the dispensary. Organized medicine, however, had long opposed this type of practice, and in 1911 the American Medical Association published an opinion on various aspects of this subject.[5] However, one physician declared very perceptively that "the unethics of contract practice depends upon the minuteness of the fee." The major questions of the times, and I might add of our time as well, were how could the poor receive adequate medical care and how could the physicians make an adequate living consonant with their educational investment and their specialized skills. As we all know,

the problems expanded, the question of voluntary or compulsory health insurance has become intrusive, and contract health care has taken on a new dimension.

This historical overview provides the perspective to examine contemporary medicine. Let me begin by summarizing the unfortunate case of Dr. Z as reported in *The New England Journal of Medicine* in August 1984.[6] The unfortunate Dr. Z had been stripped of his hospital privileges and was placed on probationary office practice because of "failure to adjust to the new medicine. He refused to accept the guiding principles of the new medicine—that the encounter with the patient, the illness episode—is accurately and completely defined by a disease diagnosis and that for every such disease there is a corresponding technological treatment." Dr. Z insisted that the patients came to him for many reasons other than the presence of a specific disease. He always seemed to be bogged down in the process of health care delivery—in taking care of the patient, as he puts it, instead of stressing outcome. Dr. Z further asserted that "in addition to providing scientific expertise physicians should express concern about their patients, gain their confidence and co-operation and give them and their families peace of mind." The answer, of course, to Dr. Z is that "we have no code or audit criteria for explanation or reassurance or what he called personal care."

Unfortunately, despite mandatory attendance at indoctrination sessions, Dr. Z seemed incapable of understanding and participating in the new mission of hospitals and thus the loss of his hospital privileges. He was never able to think of medicine as an industry and view a hospital as a business. His opposition to the dropping of the teaching program was particularly offensive.

Obviously Dr. Z is wrong. Hospitals are a business. The bottom line is "whether the doctor can contribute to the hospital's overall marketing plan." Cost accounting must be part of physicians' grand rounds. We can no longer look at patients as persons but must view them as output or input or as products. We must learn to manage product lines. Obviously Dr. Z had felt the impact of "monetary disincentives" when he lost his hospital privileges. He was then subjected to thinking adjustment sessions and given training in computer coding, advertising, market analysis, and selling strategy. Unfortunately, he reverted to his "old habits." He clings to the archaic belief that medicine is an ethical rather than a commercial enterprise. Our proposed time frame for developing his new mind set is short. If he cannot adapt to the new medicine, this is too bad, there are plenty coming along who will.

Is medicine still an art? I agree with Truman G. Schnabel who stated in an essay in *The New England Journal of Medicine* "medicine's art lies in a skillful manipulation of the relationship between doctor and patient which when combined with the logical use of medicine's science will lead to the best kind of patient care."[7] Unfortunately, the very achievements in medicine that have provided us not only with clues to disease but the means to cure them have diminished the esteem that physicians had enjoyed for many years. Technology has intruded into the practice of medicine, and the manner in which we deal with patients seems to have become less important. This era of technologies and the use of computers will have a significant impact on the doctor-patient relationship.

Another aspect of medical care that is known to all of you is that patients themselves assume more and more responsibility in the decision-making process. It seems to me that for the correct decision to be made the doctor-patient relationship must be *closer* than ever. The doctor and the patient must be able to communicate in a logical and understandable way and over a considerable period of time. Clearly, with the challenge of patient responsibility the physician must be even more sympathetic and kind and the art of medicine must be as important as its science. That this is not the case is indicated by a 1983 poll commissioned by the American Medical Association that revealed that 62% of persons in this country are losing faith in physicians.[8] Responders indicated that physicians are too interested in money and not interested in their patients. For the specialist the process of a correct diagnosis becomes almost an end in itself. Actually, the patient only wants to feel better. The message patients receive is that of an impersonal, technically dominated medical care system. The fact that the health care provided may be improved does not seem to be as important as what might be considered a "hidden message" that the machine has become the physician, the definitive advisor. Predictably this leads to the development of the "too ept" physician. We have peer review to cover the inept physician, but I believe we need a different charge to these committees that will judge the too ept—that is, the medical zealots. For those of us dealing with cancer patients it is clear that we need a new understanding of medical technology. As Crawshaw[9] said so well "by curious inversion of human values, scientific therapeutic zeal has become a new dangerous iatrogenic disease—the technical fix. Caught up in the wonderment of burgeoning technology, physicians become blind to the difference between physiology and life." This technical fix is becoming widespread. Unless we are careful there will be an irreversible distortion of our humanity.

Before discussing the changing monetary aspects of medical care, let me complete the historical review with a few words about the controversy over physician supply. There is some evidence that market forces are responding to a perceived surplus of physicians. Some

medical schools are reducing enrollment, and certainly all medical schools are feeling the decrease in reduced federal funding. On the other side of the ledger is the increasing cost of medical education. A recent American Medical Association survey showed that some 60% of physicians in practice 2 years or less have educational loans outstanding. Additional market forces were recognized by the Rand Corporation that showed that increasing numbers of physicians are locating their practices in smaller communities and that Americans in nearly every community with a population of at least 2500 now have ready access to a physician. Because there is no certain way to predict the future needs of physician manpower, the educational system for physicians should not be locked into a rigid system of quotas or limits. With the market forces now at work the present system will resolve most of the problems associated with the fluctuations in the economy and an increase in physician population. Citizens with freedom of choice rather than centralized planners are more likely to develop and make use of information necessary to allow the market place to function effectively.

The major health manpower issue facing the United States is not an excess of physician supply but an excess of specialist physicians. Because we have so many specialists, we rely on some to do primary care, but because of temperament and training they may not be educationally prepared to function as a generalist physician. In the United States there is an unusually high rate of operations and invasive procedures. There is no waiting list for any procedures, and certainly there is no shortage of surgeons.

Having described the complex relationship between physicians, hospitals, and universities and the social conditions of a hundred years ago that initiated changes in medical practice, it is appropriate to review what can be called the "monetarization" of medical care and entrepreneurism in medicine. A number of observers have expressed alarm at how fast American medicine appears to be turning from a profession into a business. The monetarization of medicine as defined by Ginsberg[10] is the "rapid penetration since 1950 of the money economy into all facets of the health care system." Its influence is reflected in the growth of academic health centers, the shift from voluntary employer physicians in large teaching hospitals, the payment of what appear to be reasonable stipends to house staff, the marked decline in philanthropy in meeting operating deficits, and the substantial reduction in unrequited services by physicians.

In the 1940s, medicine was only partly monetarized. However, rapid expansion in hospital insurance and the enactment of Medicaid programs in 1965 set the stage for the complete monetarization of health care. Although the major impact of this was and remains on the hospital sector, physicians surely are the critical and ultimate providers of care. I believe we cannot view the practice of medicine as just another business undertaking like retailing or banking. To rely on the market to discipline professionals is to overestimate what the market should be asked to do or indeed is capable of doing. There are critics and defenders of this growth of the for-profit sector in medicine. Relman[11, 12] maintains that these profits result from nothing less than the buying and selling of assets and the avoiding of unprofitable activities such as teaching and care for the poor. Defenders predictably emphasize gains from access to more capital, improved planning and operating systems, and more "professional" management.

A further development of this monetarization is the entrepreneurism of medicine exemplified by hospitals organizing a variety of corporations that spin off traditional services and joining or competing with doctors and other hospitals in new ventures such as health maintenance organizations, preferred provider organizations, surgery centers, and clinics in shopping malls. The major difference here is that in the usual business venture investors risk their own money. In this situation, not only is someone else's money being risked, but the very institutions that we depend on to provide services may also be at risk. Part of the problem is the hysteria associated with the high cost of medical care and its perceived shortcomings—however, these services still provide the best medical care available in the world. I believe that the American public will not permit a system that encourages bottom line quality and a price competition environment rather than personal care.

In any system, care of the disadvantaged is the central problem. It is worth remembering that in spite of all the skills that may be developed, including marketing, diversifying, and maneuvering of hospitals, unless these resources accommodate the needs of the unserved and the underserved, the health care system will be overturned no matter how efficiently it may serve those who can afford it. As Cunningham[13] has stated, "there appears to be two possibilities—less competition of the kind of government, industry and some hospitals are pushing—or more federalization. The question is which shall it be?" Many feel that the physician and the health administration will move from the professional model with its traditions to one of professionally regulated competition. Perhaps the eighteenth century philosopher was correct in noting that "competition makes the prince rule more wisely than his wishes alone intend."

An example of the accelerating trend in for profit organization is the transformation of the health maintenance organization movement. The health maintenance organization is one form of alternative health care delivery which features some limitation on a pa-

tient's choice of physician in return for comprehensive benefits provided at a fixed price. It is clear that insurance organizations, hospital management companies, physician entrepreneurs, private business men, and the like are in the process of expanding medical plans that will compete against traditional practitioners. It is interesting that the only organizations that seem to be the least involved in this movement although they are the most threatened are the academic medical centers. One of Wall Street's highly regarded stock analysts has noted that although the health maintenance organization appears to be the ideal solution to cost escalation facing the country, few people have been willing to abandon the idea embedded in the American health care system of unlimited quality and access even when it is no longer cost effective.

There is evidence that the fee-for-service physician is not sitting idly by in the face of this competition. However, it seems certain that life will never be the same again for most practitioners, as a consequence of the new emphasis on greater price sensitivity among third-party payers. Certainly one long-range device for countering this dilemma would be the teaching of medical economics to our medical students, interns, and residents. Few if any medical schools include in their curriculum the crisis of financing medical care and certainly none exposes the doctor as the key culprit.

Let us look now at the relationship between hospital management and its medical staff under a prospective payment system. This, I believe, is the crux to understanding what I feel may be the gradual demise of academic institutions. First, we must understand the traditional relationship between hospital administration and the medical staff. Clearly, hospital management focuses on finances, and its primary goal is to keep the hospital fiscally solvent. The medical staff's primary goal is to provide patients with the best possible medical care with less regard for cost. With the new prospective payment system based on a diagnostic-specific program in contrast to the traditional cost-retrospective reimbursement, hospitals are at greatly increased financial risk. Because physicians control 60% to 70% of the health care expenditures, hospitals must convince the medical staff to adhere to "cost-effective" patterns, and the potential for this relationship between hospital and medical staff to become even more volatile is enormous. Hospital managers must be certain that each physician's pattern of use does not deviate from the narrow range of reimbursement established in each one of the current 467 clinical diagnosis related groups. Some type of sophisticated information system will be required to monitor physician behavior and correlate financial information with clinical information and then assess the cost-effectiveness of the diagnosis related groups singly and comparatively. This is quite reminiscent of the plight of Dr. Z. Once a physician has been identified or appears to exhibit a costly and inefficient behavior "he or she may be approached through education peer pressure or conceivably even restriction of privileges if the costly behavior persists." However sophisticated, aggregate hospital cost accounting does not tell us what a service really costs. Hospitals are looking at *systems* that allow comparison of various diagnoses among multiple hospitals. Cost-effective standards will have to be established for regional and national comparison. Obviously such standards once established will be used to evaluate which diagnosis related groups are cost effective for the particular institution and therefore "profitable to offer." If unprofitable diagnosis related groups are dropped, expensive tertiary services may be the first to go, especially among hospitals in the for-profit sector. Under the new Medicare prospective payment system the educational expenses of hospitals are covered. However, this system poses a distinct danger for complex care and research. Thus for the university hospital and academia in general, some feel that the new payment rules are certain to lead to a decrease in the number of university hospitals and may provide convenient means for shrinking the nation's entire medical education system. The per-case prospective payment concept has some merit because it rewards economy rather than consumption. The use of the diagnosis related groups on the other hand does not appear to be an accurate measure of the use of hospital resources, and university hospitals suffer most in systems using them.

An examination of the New Jersey experience shows that it is difficult to add new programs and equipment that are necessary to carry out teaching and research. Once rates have been established for any given period it may be impossible to change them, and when a system reaches maturity and in a sense all practical efficiencies are realized, new programs can be added only at the expense of existing ones. Unfortunately, experimentation and the unique concerns of university hospitals seldom bear fruit immediately. It would be tempting to assume this danger is averted when costs of the academic institution are passed on to the consumer under the prospective payment system. In this system, different hospitals are paid different prices according to their teaching status, presumably for an identical service. In the current price comparative area the university hospital can be expected to become only the last resort for care. Academic institutions face a dilemma. If they maintain the high and all-inclusive prices they need, they will be too expensive for consumers with a choice. If they do not maintain these high prices, then they lack the support for their special roles. Unfortunately, we do not know the true cost of patient care when separated from the cost of other services of the uni-

versity hospital, that is, education, research, and technology transfer. Who should pay for these costs? The answer, obviously, will determine the future of American medical education. It is surely true that if academic institutions continue to be funded through patient care income, the university hospital will of necessity become less comprehensive and more specialized. Like any other hospital, they will identify "product lines" of greatest profit to them, that is, the types of care they can render competitively. Other cases will be cared for elsewhere. The size and nature of the house staff will be determined by the service needs of the community rather than the dictums from the medical schools.

One academic institution, The Johns Hopkins Hospital, 10 years ago began an operation with a management structure designed to control expenditures by placing responsibility for cost in the hands of physicians. Operating responsibilities were shifted to the clinical departments. In this structure, the larger hospital in effect became a holding company for a series of specialty hospitals referred to as functional units. Each functional unit is headed by a physician-in-chief who is also the chairman of that department in the school of medicine. Reporting to this chief are a nursing director and an administrator. The three function as a management team and are accountable for all direct cost associated with the operation of the unit including services acquired from other departments, such as laboratory medicine and radiology. This has been effective in involving physicians in budgeting and budget management, and the process apparently is moving forward to allow decentralization of both revenue and expense budgeting. This approach recognizes that decisions to bring patients into the hospitals, to recommend diagnostic studies, to prescribe treatment, and to discharge patients generate the majority of hospital expenses. This decentralized management gives the responsibility for these decisions to those who make them, the physicians.

Relman[14] has raised the question "Are teaching hospitals worth the extra cost?" He points out that the average cost per adjusted admission in the more than 300 major teaching hospitals was approximately twice that in nonteaching institutions. When hospitals were paid whatever they charged, this difference in cost was no problem. However, with Medicare switching to a prospective payment system based on fixed payments according to diagnosis related groups, teaching hospitals must cut their cost if they wish to survive. Under the present system, there is no distinction between a patient in a given diagnosis related group who is treated in a nonteaching hospital and one who is treated in a teaching hospital. However, the indirect cost of the house staff and other direct and indirect costs of teaching and research are dealt with through an added calculation by a formula based on the number of house officers per bed. There is no recognition of the cost of free care in teaching hospitals under this system. It is clear, as pointed out by Relman, the special needs of the teaching hospitals will no longer be "automatically accommodated by a passive reimbursement system." Teaching hospitals must therefore convince the government and other third-party payers that their unique and expensive blend of education, research, and tertiary care is worth supporting. Relman concludes, "To survive, they, the university hospitals will need astute leadership and co-operation from the medical staffs."

What has been the reaction to these changes in health care delivery? Public acceptance of large service organizations has always been controversial. Medical care, the most personal of services, is undergoing a change to corporate status as we have noted. For example, almost one third of long-term renal dialysis is provided by one corporation. In addition to the personal nature of this service, the life and death aspects are often only remotely a matter of foreknowledge. If care is urgent, patients go to emergency rooms or tertiary care centers and very frequently cannot name their physician. Patients often say "I had my surgery at the Mayo Clinic or the Massachusetts General," but no physician's name is recalled. Apparently, confidence at times does reside in an institution as well as the individual physician.

If these medical service organizations are acceptable to the public, what effect will this have on the medical profession? Obviously, the part of the profession most susceptible to change is the pool of new medical graduates who apparently are more than adequate in number and thus face greater competition. The trend to medical practice grouping is accelerating so that by the end of the 1990s the majority of the physicians may be so well organized that the independent practitioner will be in the minority. It is suggested that as these groups serve larger populations, they may have multiple service sites and in time serve multiple cities. Each site may then be headed by physicians who "have best adapted to the corporate management style and objectives. The physicians who do not conform to the group objectives, schedules and standards feel peer pressure and stagnation of reward. Some cannot accommodate to peer monitoring and leave." This is surely reminiscent of the plight of Dr. Z in my introductory remarks.

Medical education has given very superficial attention to these changes, and it would seem to me that there must be a thorough discussion and understanding of the direction that medical schools, residency programs, and continuing education programs are headed.

Public attitudes about health care costs are interesting. A recent analysis drawn from 15 national public opinion polls conducted between 1981 and 1984 is particularly relevant. These are the facts regarding health care costs. Despite all that is being done to slow growth of health care cost in the United States, that is, enact-

ment of prospective payment for Medicare (diagnostic related groups), increasing enrollment in health maintenance organization groups (now used by 7% of the population), hospital rate setting in 12 states and other changes, the nation's health care expenditures will increase from $322 billion in 1982 to $690 billion in 1990 and to $1.9 trillion by the year 2000, that is, 14% of the gross national product. This means an average increase of $50 billion a year and a doubling of the nation's health spending every 6 years. The impact of this on the $200 billion federal deficit, the potential bankruptcy of Medicare, and the prospect of renewed inflation leading to another recession are seen as major problems by our national leadership. This year the United States will spend about $1500 per person for health care whereas Japan will spend $500, Great Britain $400, France $800, and West Germany $900.

What is the public attitude toward these facts? Briefly stated, the public opinion survey showed that Americans want the problem of rising health care cost addressed, but they are unwilling to support the adoption of any solution that would produce a dramatic change in their own medical care arrangements. The majority of Americans polled are not in favor of giving up their own personal physicians for care delivered by low-cost physician groups. In fact, a major reason why many Americans choose not to join health maintenance organizations is their reluctance to break ties with their family physician. On the other hand, the public seems to be quite enthusiastic about requiring low-income people to use less costly clinics or health maintenance organizations. The message seems to be "reorganize the nation's health care for others, but don't change my own health care arrangements."

What can be done about this situation? Leaf[15] notes that with medical cost now in excess of 10% of the gross national product, health care encroaches on support for other needs. Virtually all thoughtful studies indicate that decisions by physicians determine between 70% and 80% of all personal medical expenses and thus physicians are the key in setting priorities. However, nothing in medical tradition, training, or experience gives them any expertise to act wisely in making these choices. As Leaf has noted, "On the one hand they have the tradition of exclusiveness of the patient physician relationship and the physician's concerns solely for the patient's welfare. On the other hand, society is paying the bill, not the patient. By making medical decisions, especially those involving the use of costly technology, physicians may be torn between serving the interests of the individual and serving those of society. They have responsibilities to both."

Egdall[16] notes that physicians are being compelled by regulatory initiatives and competition from health maintenance organizations and other alternative delivery systems to reexamine traditional practice routines. It is clear that there are dangers associated with unnecessary hospitalization including the development of nosocomial infections and occurrence of iatrogenic events in hospital environments. Hospitalization obviously is the logical target of efforts to maintain the health care dollar because it is the major component of health care cost.

A number of studies have suggested that high surgical rates can be modified by informational and educational programs. One such study showed the effect of outside surveillance on the rate of hysterectomies in Saskatchewan. The proportion of unjustified hysterectomies as defined by an advisary committee was 23.7% at the time of the first review and dropped to 7.8% at the time of the second review 4 years later. There are wide variations in surgical rates and this does not suggest that surgeons with a higher rate of surgical procedures are practicing poor medicine, but it does mean that in a cost-containment environment surgeons who do not fit the consensus criteria may feel some pressure to justify their admitting patterns, given the dangers and expenses of hospitalization.

Egdall[16] suggests that these savings will come at a price, and indeed one of his suggestions certainly will not be welcomed by hospital administrators. He believes that true cost management must involve shrinkage of the hospital system or use of freed-up capacity resulting from improved practice efficiency to accommodate the needs of our aging population rather than creation of additional capacity. This combined with incentives for surgeons to practice more efficient strategies to strengthen the hospital system as occupancy falls will in his view provide the basis for major community cost containment.

I believe that the important issues in medical practice today include not only the impact of the for-profit movement, but also the trend toward abdication of responsibility and what I call the treatment imperative. It is the rule rather than the exception that patient care is associated with divided responsibility. This is true in group practices and even in the daily surgical rounds and follow-up management. One can justify these practices in the name of better patient care, accessibility, and physician alertness. This platoon system is effective in sports in which it is a question of physical stamina and specialized assignments, but the question of continuity of a process or responsibility is not addressed. I believe it is essential particularly in surgical practice for the operating surgeon to assume full responsibility for the procedure. The litigious attitude of our present society attests to the fact that patients are not entirely happy with this division of responsibility and lack of continuity by their personal physician.

The treatment imperative is particularly subtle. It is the direct result of the newer modalities in treatment with expanded use of chemotherapy and experimental

protocols and also the development of the superspecialist. Extra training implies a necessity to practice what has been learned regardless of the quality of life or the economic impact. The very nature of specialization prevents the physician from viewing his or her actions at a distance. Instead we have the dogma of the training programs—a confidence often based on inexperience and the mysterious language of the clinical trial, p values, and prospective randomized, double-blind studies. This patient is not Mrs. Jones, she is F 103. These studies are necessary, but they have taken a life of their own and frequently obscure obvious medical facts and certainly ethics.

If academia is to survive in this changing medical environment, colleges must emphasize broad intellectual accomplishments rather than a trade school, biochemical approach. Intellectual curiosity, familiarity with the spoken and written word, and yes, manners are important. Medical school deans and admission committees must revise their criteria for admission to include those candidates with a genuine interest in people and patient care in addition to their intellectual achievements as measured by the Medical College Admission Test and their grades. Specialty boards must take a careful look at what they have accomplished. Has the superspecialist become the intellectual automaton acting only on the basis of what he is trained to do for the patient? It is important for us to remember that the pelvic surgeon to women must not be the ambidextrous product of a technical assembly line programmed for increasingly narrow medical skills and intellectual curiosity.

Earlier, I discussed the social conditions of a hundred years ago, the oversupply of physicians, and the increasing dichotomy between the hospital-based physician and the family practitioner. The present drive toward superspecialization, divided responsibility, and the rapid growth of for-profit medical facilities may dissuade the public from any long-range approaches to the problem of rising health care costs including dramatic medical breakthroughs and major positive changes in life-style. They will instead move to short-term solutions—regulation including capital investment controls, state hospital rate setting, and reimbursement controls, competition with the restructuring of health insurance benefits, and the development of alternative health plans and preferred provider organizations that will severely penalize academic institutions and tertiary centers leading to the demise of academic medicine.

None of us has all the answers to control increasing health cost and in particular, hospital care. It is clear that some medical benefits will have to be withheld, at least for some patients. Given this possibility, who will decide which patient is entitled to treatment and what criteria will be used to make this choice? This limitation of medical resources places physicians in an awkward situation. Neither our training nor our long cherished code of ethics prepare us to make such decisions in economic terms.

I began this essay by discussing the plight of physicians at the turn of the century. It is interesting that in a survey of the health care system in Britain, philanthropy continues to play an important role in selected fields of health care, particularly the donation of expensive medical equipment such as the computerized tomographic scanners and the like. Also because of dissatisfaction on the part of the private practitioner, the national health service hospitals retain a few beds for paying patients and the system permits its consultants to have part-time private practice. It appears that we have come full circle and perhaps the lessons of the past will lead us toward a solution of this fiscal and ethical dilemma. We must not be committed to one or another proposal as the *only* solution to rising health care costs. Our allegiance to a single solution stands in the way of a national effort to solve this problem. We must build a consensus around a cost-containment program that realistically reflects public opinion and satisfies the professional and ethical concerns of physicians. Failure to act promptly and decisively surely will hasten the demise of academia—the foundation on which effective health care must stand.

Effect of low-dose aspirin on angiotensin II pressor response in human pregnancy

Luis Sanchez-Ramos, M.D., Mary Jo O'Sullivan, M.D., and Jose Garrido-Calderon, M.D.
Miami, Florida, and Santo Domingo, Dominican Republic

Recent clinical studies have reported a significant reduction in the incidence of pregnancy-induced hypertension after the ingestion of low-dose aspirin. The effect of 80 mg of acetylsalicylic acid on vascular sensitivity to exogenous angiotensin II (Hypertensin, Ciba-Geigy Limited, Basel, Switzerland) was examined in 13 normotensive pregnant patients. The effective pressor dose before treatment (17.4 ± 2.2 ng/kg/min) (mean ± SE) was significantly less ($p < 0.001$) than that after treatment (35.1 ± 4.2 ng/kg/min). Low-dose aspirin therapy resulted in an enhancement of the pregnancy-acquired refractoriness to angiotensin II. It can be speculated that prostglandin synthetase inhibitors at a low dose may alter the thromboxane A_2/prostacyclin ratio in favor of the latter. (Am J Obstet Gynecol 1987;156:193-4.)

Key words: Angiotensin II sensitivity, preeclampsia, aspirin

During normal human pregnancy, as early as the first trimester, there is marked refractoriness to the pressor effects of infused angiotensin II. In women destined to develop pregnancy-induced hypertension, this refractoriness is lost as early as 22 weeks' gestation.[1, 2]

Why refractoriness to angiotensin II occurs is unknown. It has been suggested that this refractoriness is prostaglandin mediated. Studies with the use of moderate doses of prostaglandin synthetase inhibitors before and after angiotensin II infusion in pregnant women have shown a significant decrease in the effective pressor dose of angiotensin II, demonstrating increased angiotensin II sensitivity in all patients studied.[3, 4]

Low-dose aspirin is capable of inhibiting thromboxane A_2 production with minimal effect on the synthesis of prostacyclin, thus possibly restoring a critical thromboxane-prostacyclin balance.[5]

Recent studies have shown that aspirin may prevent pregnancy-induced hypertension by inhibiting thromboxane A_2 production.[6, 7]

The purpose of this study was to pursue whether low-dose aspirin would affect angiotensin II sensitivity.

Material and methods

Thirteen primigravid women participated in the study. They were all 28 to 34 weeks' gestation and had no evidence of hypertension or of cardiac or renal disease. The patients were recruited from the antenatal clinics at the Maternity Hospital of the Dominican Institute for Social Services in Santo Domingo, Dominican Republic. Informed consent was obtained from all patients after the study was formally approved by the Maternity Hospital's Committee on Human Investigation.

The patients were placed in a quiet room in the left lateral position for the duration of the study. Blood pressure measurements were obtained every 5 minutes until a stable diastolic pressure was achieved for 15 minutes, by means of a standard sphygmomanometer on the left upper arm. The first and fifth sounds of Korotkoff were recorded as the systolic and diastolic pressure, respectively. An infusion of angiotensin II (Hypertensin, Ciba-Geigy Limited, Basel, Switzerland) was administered with an infusion pump (Model No. 1001, MED Fusion Systems, Inc., Norcross, Georgia). The infusion contained 50 μg of angiotensin II in 50 ml of 5% dextrose in water (1 μg/ml) and was started at a rate of 4 ng/kg/min. The dose was increased by small increments every 5 minutes until the minimum amount of angiotensin II that increased the diastolic pressure by 20 mm Hg was reached (the effective pressor dose).

When the effective pressor dose was established and maintained for 2 to 3 minutes, the angiotensin infusion was discontinued and the diastolic blood pressure was allowed to return to its baseline value. Confirmation of the effective pressor dose was established by restarting the angiotensin II infusion at the same rate that had previously elicited a 20 mm Hg increase in the diastolic pressure.

After the validity of the pretreatment effective pressor dose of angiotensin II was established, the infusion was discontinued and each patient was given 80 mg of

aspirin. Two hours later, the angiotensin II infusion was restarted to establish the effective pressor dose after low-dose aspirin in the same manner as before the treatment.

Results

Thirteen primigravid women, 28 to 34 weeks' gestation, were studied before and after the administration of low-dose aspirin (80 mg). The effective pressor dose of angiotensin II in each of these patients was greater after treatment than before. The mean ± SEM pretreatment value of the group was 17.4 ± 2.2 ng/kg/min and increased to 35.1 ± 4.2 ng/kg/min, which is significantly greater than pretreatment levels ($p < 0.001$). Each patient studied demonstrated a blunted pressor response with low-dose aspirin (Table I).

Comment

The results of the present study demonstrate a significant decrease in angiotensin pressor responsiveness (increased refractoriness) 2 hours after oral administration of 80 mg of aspirin to apparently normal primigravid women in the third trimester of pregnancy. This is in contrast to previous reports that found enhanced sensitivity to angiotensin II after higher doses of prostaglandin synthetase inhibitors.[3, 4]

This discrepancy may be due to selective inhibition of platelet-derived thromboxane A_2 by low-dose aspirin in contradistinction to the inhibition of both thromboxane A_2 and prostacyclin with higher doses of prostaglandin synthetase inhibitors. Aspirin, ≥40 mg/day, inhibits both vascular wall prostacyclin production and platelet thromboxane production, but the effect of aspirin on thromboxane A_2 is greater.[5, 9]

Alterations in the production of prostaglandins may play an important role in the pathogenesis of pregnancy-induced hypertension. An imbalance in opposing actions of thromboxane A_2 and prostacyclin on platelet aggregation and vessel tone may be responsible for some of the clinical and laboratory manifestations of preeclampsia. Thromboxane A_2 is a potent vasoconstrictor and stimulator of platelet aggregation by the placenta and platelets, whereas prostacyclin is a vasodilating agent with opposing effects on platelet activity.[7] Enhanced sensitivity to angiotensin II, causing decreased refractoriness, may be the first sign of such an imbalance, which is tilted in favor of thromboxane A_2. Unfortunately serum and/or urinary levels of the principal metabolites of thromboxane and prostacyclin were not determined in the clinical studies cited or in any of the reports, including ours, on the effects of prostaglandin synthetase inhibitors on the pressor response to angiotensin II. We are currently undertaking such a project.

This study serves to strengthen the theory that pregnancy-related refractoriness to angiotensin II may be mediated by the action of prostaglandins and suggests the possibility that low-dose aspirin may affect prostaglandin imbalances and thus contribute to the reduction of the sensitivity to vasoactive agents characteristic of preeclampsia.

Deoxyribonucleic acid hybridization analysis for the detection of urogenital *Chlamydia trachomatis* infections in women

Chia C. Pao, Ph.D., Shyh-Shyan Lin, M.S., Tsyr-En Yang, M.S., Yung-Kuei Soong, M.D., Pai-Shun Lee, R.N., and Jung-Yaw Lin, Ph.D.

Taipei, Taiwan, Republic of China

The presence of *Chlamydia trachomatis*–related deoxyribonucleic acid sequences in endocervical specimens of 317 women was analyzed by deoxyribonucleic acid hybridization techniques with deoxyribonucleic acid from *C. trachomatis* used as probes. Samples from 56 of 172 high-risk patients (32.6%) and 16 of 145 low-risk patients (11.0%) contained *C. trachomatis*–related deoxyribonucleic acid sequences. Direct detection of chlamydial antigen with enzyme-linked immunoassay on the same patients yielded positive rates of 26.3% and 7.3% for the high- and low-risk patients, respectively. *C. trachomatis* culture confirmed 86.3% of deoxyribonucleic acid–positive results and 84.0% of antigen-positive results. The overall sensitivities of chlamydial deoxyribonucleic acid and antigen assays were 91.7% and 68.8%, respectively, whereas the specificities were 95.3% and 94.7%. Results also suggested that the test of the *C. trachomatis* deoxyribonucleic acid correlated better with the female urogenital chlamydial infections than did the antigen test of *C. trachomatis*. The combined results of higher sensitivity in detecting the microorganism and better correlation with disease activity may make the deoxyribonucleic acid hybridization test a useful tool for the early and accurate diagnosis of *C. trachomatis* infections in female patients. (AM J OBSTET GYNECOL 1987;156:195-9.)

Key words: *Chlamydia trachomatis*, female urogenital infection, deoxyribonucleic acid hybridization, deoxyribonucleic acid probe

Infections caused by *Chlamydia trachomatis*, now recognized as the most prevalent of all sexually transmitted diseases, are very damaging and can result in a wide range of diseases including trachoma and lymphogranuloma venereum.[1-3] Men, women, and infants are all affected, but women bear a disproportionately heavy burden because of their increased risk for other adverse reproductive consequences. In women, *C. trachomatis* may cause mucopurulent cervicitis and urethral syndrome in the lower urogenital tract and endometritis and salpingitis in the upper urogenital tract. These infections can also result in sterility and other complications during pregnancy.[3-5] Although chlamydial infections can now be effectively treated with antibiotics, one of the most difficult aspects of controlling chlamydial infection in women is that unrecognized and misdiagnosed chlamydial infections in women are common. It has been suggested that a substantial portion of women infected with chlamydiae may be asymptomatic.[2, 3]

Chlamydiae possess a unique development cycle. Although they are now classified as bacteria, they share many properties with viruses. Chlamydiae are obligatory intracellular parasites and depend on the energy supply of the host cells to grow.[6] For this reason, culture of chlamydiae is laborious and requires tissue culture techniques and facilities. Time and expenses are increased further when subculturing is needed, which is quite often. Therefore the culture method has not become routine procedure in the laboratory diagnosis of chlamydial infection. Direct cytologic staining is available, but it has only limited applications because of its lacking of specificity and it requires a considerable amount of experience if false positive and false negative results are to be avoided. In recent years, antigen detection methods, such as direct-smear immunofluorescence staining tests[7] and enzyme-linked immunoassays,[8] have improved rapidly; these offer an alternative to the conventional culture and cytologic staining methods and open the door to further investigation of the broad spectrum of diseases caused by this microorganism.

In the following text, we report the use of deoxyribonucleic acid (DNA) fragments from the human biovar strain of *C. trachomatis* in a DNA hybridization test on clinical specimens to determine its value as a reliable culture-independent diagnostic test in the detection of chlamydial infection. The DNA hybridization test was found to have compared favorably with the conventional culture and antigen results.

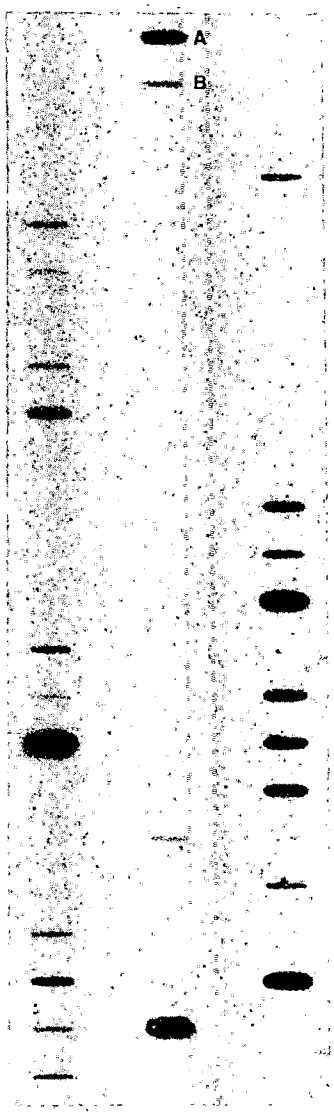

Fig. 1. Autoradiographs of the chlamydial DNA slot blot hybridization test of endocervical samples. Shown here are the DNA results of 60 patients participating in this study. Specimens were treated and handled according to the procedures outlined in Material and methods. The actual size of each slot was 0.75 by 8 mm, or 6 mm^2. Slots *A* and *B* were positive controls of 20 and 2 pg of chlamydial DNA, respectively.

Material and methods

Study protocol. Individuals visiting the outpatient clinic of the Department of Obstetrics and Gynecology of the Chang Gung Memorial Hospital in Taipei, Taiwan, were recruited for this study. A total of 172 patients who had signs or complaints of one or more of the following symptoms were included in the high-risk group: primary infertility (65 patients), urethritis or urethral syndrome (29 patients), cervicitis (10 patients), cervical erosion (nine patients), pelvic inflammatory disease (53 patients), tubal disorders (15 patients; 12 confirmed by laparoscopy and three suspected), pr vious ectopic pregnancy (six patients), recurrent or h bitual abortions (24 patients), and previous stillbirth c neonatal death (three patients). Another 145 patien who were matched in age and in marital and socioec nomic status and who visited the clinic for reasons othe than those listed above were selected as the lov risk group. Informed consent was obtained from a patients.

Laboratory procedures. Two endocervical and/c urethral swabs were collected with the STD-EZE swa (Abbott Laboratories, Inc., North Chicago, Illinois). E tracts from the swabs were pooled and divided in three equal portions for chlamydial DNA, antigen, an culture analysis. Blood samples were also drawn f antichlamydial antibody determination. Chlamydial a tigen was determined by the enzyme-linked immun assay kit Chlamydiazyme, commercially obtained fro Abbott.[8] Antichlamydial antibody was assayed wit an enzyme-linked immunoassay kit obtained fro Exdevelop Pharma, Täby, Sweden. Chlamydial DNA i the endocervical swab was determined by a modifie DNA:DNA hybridization technique that we have pr viously used for the quantitation of hepatitis type virus DNA,[9] which was based on methods initially d scribed by others.[10] Briefly, a purified cloned chlamydi plasmid DNA of 6.7 kilobases, pLGV125,[11] consistin only of the chlamydial plasmid genome was used probe. This DNA was originally cloned by Dr. St ven H. Larsen of Indiana University School of Medicir and was kindly made available to us. Alternatively, cloned DNA coded for the major outer membrane pr tein of *C. trachomatis* serovar L2, pFEN207,[12] obtaine from Dr. F. E. Nano of Rocky Mountain Laboratori was used as a probe. The DNA probe was labeled wit [alpha-^{32}P]-deoxycytidine 5′-triphosphate by nick tran lation of the purified chlamydial DNA to approximate 1×10^8 cpm per microgram of DNA. DNA from e docervical material was extracted with phenol and d natured with 40 μl of sodium hydroxide, 2 mol/L, an sodium chloride, 2 mol/L, for 10 minutes at room ten perature. Then 75 μl of Tris hydrochloride, 1 mol/l pH 7.4, and sodium chloride, 4 mol/L, was added neutralize the reaction mixture. Each specimen w deposited on a 0.45 μm pore size nitrocellulose men brane filter sheet through wells of a microsample fi tration manifold under vacuum (BA85 and Min fold II, both from Schleicher and Schuell, Inc., Keen New Hampshire). After loading, the nitrocellulose filt was gently removed from the manifold under conti ued vacuum, blotted, air dried, and baked at 70° C f 2 hours in vacuo. DNA hybridization was performe at 65° C with about 2×10^7 cpm of the labeled DN used as probe for each filter of 63 by 228 mm in siz After prehybridization and hybridization, the filte

Table I. Prevalence of chlamydial DNA, antigen, culture, and antichlamydial antibody in high- and low-risk women

	High risk		*Low risk*		*Overall*	
Type of assay	*n*	%	*n*	%	*n*	%
Chlamydia DNA	56/172	32.6*	16/145	11.0*	72/317	22.7
Chlamydia antigen	35/133	26.3†	9/124	7.3†	44/257	17.1
Chlamydia culture	39/106	36.8‡	9/92	9.8‡	48/198	24.2
Antichlamydia antibody	29/152	19.1§	18/117	15.4§	47/269	17.5

Percentages represent prevalence, which is equal to number of patients with positive results per number tested in each assay and patient group.

*$\chi^2 = 20.68$, $p < 0.001$.

†$\chi^2 = 16.35$, $p < 0.001$.

	Low	44.4	4/9	94.0	78/83
	Overall	68.8‡	33/48	94.7	142/150

*Sensitivity = number of samples that were DNA and culture positive or antigen and culture positive per number of samples that were culture positive.

†Specificity = number of samples that were DNA and culture negative or antigen and culture negative per number of samples that were culture negative.

‡$\chi^2 = 7.94$, $p < 0.01$.

were washed sequentially in 2X SSC, 0.1% sodium dodecyl sulfate, 30 minutes twice at room temperature (1X SSC = sodium citrate, 15 mmol/L, and sodium chloride, 150 mmol/L, pH 7.0); 0.1X SSC, 0.1% sodium dodecyl sulfate, also 30 minutes twice at room temperature; and 0.1X SSC, 0.5% sodium dodecyl sulfate, 30 minutes twice at 65° C. Filters were then air dried and autoradiographed for 24 to 48 hours. After autoradiography, the filters were cut out and counted in a liquid scintillation counter. The amount of chlamydial DNA in the swab samples was calculated according to the chromic phosphate P 32 counts obtained from a series of dilutions of purified chlamydial DNA prepared from a stock of known concentration and hybridized to the probe DNA on the same filters. The sensitivity of detection of our method was determined to be approximately 1.0 pg of chlamydial DNA. For the purpose of analyzing the results, a DNA concentration readout of ≥2.0 pg was interpreted as a positive result in this study (Fig. 1).

Culture for chlamydia was performed with the use of cycloheximide-treated McCoy cell monolayers as described in detail elsewhere.[13]

Results

The incidence of endocervical chlamydia with the DNA, antigen, and culture techniques as well as the finding of serum antichlamydial antibody is shown in Table I. The incidences displayed by the high-risk patients were significantly higher than those from the low-risk group in three of four categories, excepting antichlamydial antibody, where the difference between the high- and low-risk groups was not significant. The overall positive rates for DNA and culture were close, and both were significantly higher than the positive rate for chlamydial antigen (Table I). The two DNA probes, pLGV125 and pFEN207, gave essentially the same results. The mean age of the infected participants, based on either the DNA, antigen, or culture findings, did not differ significantly from the mean age of those who were not infected.

A comparison of sensitivity and specificity of the DNA and antigen tests is presented in Table II. The overall sensitivity was 91.7% for the DNA test and 68.8% for the antigen test ($p < 0.01$). On the other hand, the DNA and antigen tests showed equally high degrees of specificity. The overall specificity was 95.3%

for the DNA test and 94.7% for the antigen test. On the basis of an average incidence of 22.7% for the DNA test and 17.1% for the antigen test, the predictive values of positive results were 86.3% and 84.0% for the DNA and antigen tests, respectively. For negative results, the predictive values were 97.3% and 90.4%.

For 198 patients with a complete set of DNA, antigen, and culture test results available, the discordance between culture results and those of antigen and DNA was analyzed. (1) Of the 150 culture-negative patients, eight were found to be antigen positive and seven were DNA positive. The chlamydial DNA concentrations in the endocervical specimens of these seven patients were below 20% of the mean DNA concentrations of all patients tested, and four of these seven patients responded to treatment. The endocervical chlamydial DNA tests became negative 2 weeks after the patients were treated with Vibramycin. If these four patients were infected, the resolved sensitivity of the DNA test would be 92.3% instead of 91.7% (Table II). (2) Among the 48 culture-positive patients, as many as 15 were not recognized by the chlamydial antigen test, and four were negative for the DNA test. Of these 15 culture-positive/antigen-negative patients, 14 were found to have chlamydia on DNA testing. (3) Fourteen of 21 patients who were antigen negative but had chlamydial DNA were confirmed to have chlamydial infection on the basis of culture results. On the other hand, only three of 11 patients who were antigen positive but with no DNA in the endocervical specimens had confirmation of chlamydiae by culture.

Comment

Several lines of evidence indicated that the higher sensitivity of the DNA method was accompanied by a better reflection of the actual disease status: (1) Chlamydial DNA sequences could be detected in none of the specimens from the eight patients with false positive antigen results; (2) specimens from 14 of the 15 patients with false negative antigen results (93.3%) contained chlamydial DNA; (3) the respective culture confirmation rates for the patients with chlamydia antigen-negative/DNA-positive and antigen-positive/DNA-negative results were 66.7% (14 of 21) and 27.3% (3 of 11) ($\chi^2 = 4.36$, $p < 0.05$). The possibility of using the DNA probe to detect chlamydiae in clinical specimens such as endocervical materials was further supported by the report that the chlamydial plasmid DNA used here as a probe, pLGV125, had extensive homologous DNA sequences in all 15 *C. trachomatis* serovars.[11] In addition, little if any DNA homology could be detected with bacteria of other genera that were likely to be present in locations where chlamydiae might be found.[14]

The 68.8% overall sensitivity achieved by the enzyme-linked immunoassay (Chlamydiazyme, Abbott) that detects an antigen of *C. trachomatis* was lower than what has been reported by others.[8] We could not rule out the possibility that this discrepancy was due to the presence of a different but very closely related antigen in our patient population. However, this discrepancy did not seem to be related to the reported cross-reactivity between Chlamydiazyme and organisms other than chlamydiae.[15]

Historically, time-consuming and expensive tissue culture techniques were required to definitively diagnose most *C. trachomatis* infections. Despite recent rapid and profound improvements in the antigen and antibody detection systems, these tests are not ideal, mainly because of their sensitivity and their lack of complete correlation with the disease activity. The usefulness of DNA:DNA hybridization has been recognized recently in the identification of a number of microorganisms and is particularly helpful in cases of infectious agents that are traditionally difficult to culture. The DNA hybridization system used here seemed to have higher sensitivity, without compromising specificity, in the detection of chlamydial infection when compared with the commercially available enzyme-linked immunoassays. Assuming a plasmid DNA length of 6.7 kilobases and 10 copies of plasmid molecules per chlamydia genome equivalent,[11] a sensitivity of 2 pg represents a level of detection of about 30,000 chlamydia genome equivalents. When the number of elementary and reticulate bodies in each infected cell is considered, the minimal number of infected cells needed for detection by the DNA probe system will actually be even lower. Such higher sensitivity could offer earlier detection and treatment of subclinical or latent chlamydial infections in women, many of whom were asymptomatic, thus reducing the incidence of serious complications and sequelae. It also opened new doors for the detection of chlamydial infections under other clinical conditions, such as during pregnancy. Chlamydial infection during pregnancy may lead to both serious sequelae in the mother and infections such as pneumonia or eye infection in infants.

In summary, results of the chlamydial DNA hybridization test showed a higher sensitivity than the antigen detection method in the diagnosis of chlamydial infections and correlated highly with the disease activity in our patient population. The results of our study indicated that the DNA hybridization test will contribute significantly to the early and accurate diagnosis of urogenital chlamydial infections in women.

We thank Dr. Delon Wu and Dr. Chau-Hsiung Chang for their interest and encouragement during this study. Appreciation is also expressed to Miss Wen-Ling Yang and Miss Ruey Ken for their technical assistance.

Divergent effects of two low-dose oral contraceptives on sex hormone–binding globulin and free testosterone

Claudia Jung-Hoffmann, M.D., and Herbert Kuhl, Ph.D.

Frankfurt am Main, Federal Republic of Germany

The effect of a triphasic combination of ethinyl estradiol and levonorgestrel on the serum concentrations of total testosterone, free testosterone, and sex hormone–binding globulin as measured directly by radioimmunoassay and on the binding capacity of sex hormone–binding globulin was compared with that of a preparation containing ethinyl estradiol and desogestrel. Blood samples were taken on days 6, 11, 21, and 28 of a control cycle, the third cycle of treatment with either ethinyl estradiol–levonorgestrel or ethinyl estradiol–desogestrel (11 volunteers each), the third cycle of a 3-month washout period, and the third treatment cycle after crossover change of the preparations. There was a significant reduction in total testosterone by 16% during treatment with both preparations. Ethinyl estradiol–desogestrel increased the concentration (+175%) and bindig capacity (+330%) of sex hormone–binding globulin to a much greater extent than with ethinyl estradiol–levonorgestrel (+92% and +160%). Contrary to this, a significant suppression of non–protein-bound testosterone by 35% was found during treatment with both oral contraceptives. The results demonstrate that an excessive elevation of the levels of sex hormone–binding globulin above the normal range does not cause a corresponding suppression of free testosterone. It is assumed that the decrease in the apparent binding affinity of high sex hormone–binding globulin concentrations to testosterone may be due to protein-protein interactions. (Am J Obstet Gynecol 1987;156:199-203.)

Key words: Low-dose oral contraceptives, sex hormone–binding globulin, testosterone, free testosterone

Non–protein-bound testosterone, which is assumed to be the biologically active testosterone fraction in serum, is a function of total testosterone and sex hormone–binding globulin (SHBG) levels. It was found that the calculation of the ratio of testosterone to SHBG ("free androgen index"), when compared with total testosterone, provides a more reliable parameter in assessing androgen status in hirsute women.[1,2] Treatment with ethinyl estradiol was found to increase SHBG concentrations in a dose-dependent manner while androgens and nortestosterone-derived progestogens exert a suppressive effect. Therefore, treatment of hirsute women with suitably composed oral contraceptives was recommended for the improvement of androgenetic manifestations.[3]

It has been suggested that the extent of elevation of SHBG correlates negatively with the free testosterone level and positively with the clinical effect.[4] Consequently, it has been claimed that oral contraceptives that cause an excessive increase in serum SHBG should be the first choice for women with symptoms of hyperandrogenism of ovarian origin. The free androgen index, however, is a derived value, and there is some doubt whether this holds true.

In contrast to desogestrel, levonorgestrel has been shown to counteract in a dose-dependent way the stimulatory effect of ethinyl estradiol on hepatic SHBG production.[5-7] As we are capable of measuring directly the serum concentrations of free testosterone, total testosterone, and SHBG by means of radioimmunoassays, we investigated the effect on these parameters of a triphasic combination of ethinyl estradiol and levonorgestrel and a preparation containing ethinyl estradiol and desogestrel, which is known to increase SHBG levels excessively.

Material and methods

Subjects. Twenty-two healthy volunteers, aged 24 to 35 years, participated in the study. Informed consent was obtained. The women had not used hormonal contraceptives for at least 3 months before the study and were not receiving pharmacologic therapy that would interfere with the study. An internal gynecologic examination, including a Papanicolaou smear, was carried out before the selection of the subjects. During a control cycle preceding the study, ovulation was confirmed to have taken place by the determination of the serum progesterone level (>3 ng/ml) on days 19 to 22 of the cycle.

Preparations. The combined triphasic preparation contained 30 μg of ethinyl estradiol plus 50 μg of levonorgestrel (6 days), 40 μg of ethinyl estradiol plus 75 μg of levonorgestrel (5 days), and 30 μg of ethinyl estradiol plus 125 μg of levonorgestrel (10 days) (Triquilar, Schering AG, Berlin, Federal Republic of Ger many). The other combined preparation contained 3(μg of ethinyl estradiol plus 150 μg of desogestrel (2 days) (Marvelon, Organon GmbH, Oberschleissheim Federal Republic of Germany).

Study design. Single blood samples were obtaine(on days 6, 11, 21, and 2E of the control cycle precedin the first treatment cycle (Control 1). Eleven wome were randomly assigned to use at first the triphasi ethinyl estradiol–levonorgestrel preparation and an other 11 volunteers were designated to use the ethiny estradiol–desogestrel preparation, each for 3 months The randomization procedure was carried out b means of a random permutations table, the odd num bers being assigned to the first group and the eve numbers to the other. The first treatment perio was followed by a washout period of 3 months (Con trol 2). Thereafter the contraceptive preparations wer changed in a crossover fashion; that is, the first grou was now assigned to use the ethinyl estradiol–desoges trel contraceptive for 3 months, and the second group the triphasic ethinyl estradiol–levonorgestrel prepa ration. Single blood samples were also taken at 8:00 AM on days 6, 11, 21, and 28 of the third treatment cycle the third washout cycle, and the third treatment cycl after the crossover of the preparations.

Laboratory methods. After centrifugation of th blood samples, the serum was frozen and stored a −20° C until laboratory analyses. Serum concentration of testosterone were measured by means of a "direct radioimmunoassay kit supplied by Sorin Biomedic (Hamburg, Federal Republic of Germany). The assa range was 0.87 to 34.7 nmol/L; the mean intra-assa coefficient of variation, 7.2%; and the mean inter assay coefficient of variation, 8.1%. Cross-reaction were as follows: 5α-dihydrotestosterone, 7.2%; andro stenedione, 0.8%; dehydroepiandrosterone, 0.036% 5α-androstan-3α,17β-diol, 0.03%; and other steroids <0.02%.

Serum concentrations of SHBG were determine with the use of a "liquid-phase" immunoradiometri assay kit supplied by Farmos Diagnostica (Oulunsalc Finland). The assay range was 6.25 to 100 nmol/L; th mean intra-assay coefficient of variation, 3.2%; and th mean interassay coefficient of variation, 5%. No huma serum protein is known to cross react with the double antibody combination used in the assay. The bindin capacities of SHBG in serum were measured accord ing to the method described by Hammond and Läh teenmäki[8] with tritiated 5α-dihydrotestosterone used a marker. The mean intra-assay coefficient of variatio was 6.6% and the mean interassay coefficient of vari ation was 8.1%. The free testosterone fraction was de termined by means of a solid-phase radioimmunoassa

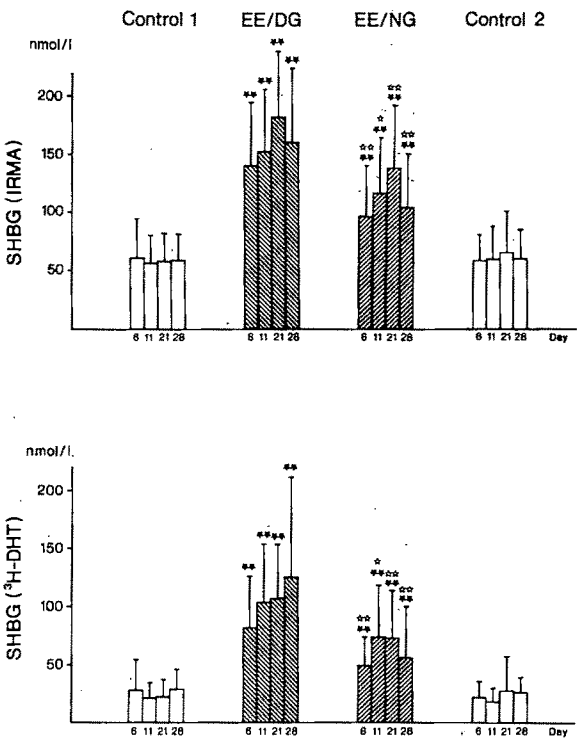

Fig. 2. The effect of ethinyl estradiol–desogestrel *(EE/DG)* and of ethinyl estradiol–levonorgestrel *(EE/NG)* on the serum concentration of SHBG (by immunoradiometric assay, *IRMA*) and on the binding capacity of SHBG (by tritiated dihydrotestosterone, *³H-DHT*) (mean ± SD). ⋆⋆ = Different from control group, $p < 0.01$. ⋆ = Different from *EE/DG*, $p < 0.05$. ⋆⋆ = Different from *EE/DG*, $p < 0.01$.

(Coat-A-Count Free Testosterone) supplied by Diagnostic Products Corporation (Los Angeles, California) with the use of an antiserum with an affinity for testosterone slightly less than that of SHBG. The assay range was 5.2 to 173 pmol/L; the mean intra-assay coefficient of variation, 3.8%; and the mean interassay coefficient of variation, 4.2%. Cross-reactions included: 5α-dihydrotestosterone, 0.041%; androstenedione, 0.01%; 5α-androstan-3β,17β-diol, 0.005%; Δ^5-androstene-3β-17β-diol, 0.007%; 5α-androstan-3,17-dione, 0.001%. There was no effect of an increase in the albumin level by 25%.

Statistical analysis. Data were analyzed by univariate analysis of variance by application of a three-factor experiment with repeated measurements on two-factor design.[9, 10] The volunteers were assigned to two groups depending on the sequence of administration of the drugs. Within-group factors were treatment comprising the four levels of control, ethinyl estradiol–levonorgestrel preparation, washout, and ethinyl estradiol–desogestrel preparation and the days of the cycle (days 6, 11, 21, and 28). A posteriori contrasts were tested by Scheffé's procedure with use of the appropriate error terms as described in detail by Glaser.[10] The level of significance was set at 0.05. The calculations were carried out on an Apple IIe computer.

Wilcoxon's matched-pairs signed-ranks test was used for the evaluation of the significance of differences between mean values on the respective days. The inverse correlation between the concentrations of SHBG and free testosterone was evaluated by calculation of the regression curves (second order) after transformation to the regression line: log (concentration SHBG) = A + B × X (concentration free testosterone), with the use of a computer program.

Results

During treatment with both ethinyl estradiol–levonorgestrel and the ethinyl estradiol–desogestrel preparation there was a significant ($p < 0.05$) reduction in total testosterone by 16% to average values between 1.11 and 1.42 nmol/L (Fig. 1).

The SHBG concentration as determined by immunoradiometric assay was significantly increased on an average from 60.2 ± 27.2 to 115.5 ± 48.5 nmol/L (+92%) by the triphasic preparation and to 165.9 ± 57.8 nmol/L (+175%) by the ethinyl estradiol–desogestrel combination (Fig. 2). The difference between both preparations was significant. The SHBG binding capacity, as determined by means of the tritiated 5α-di-

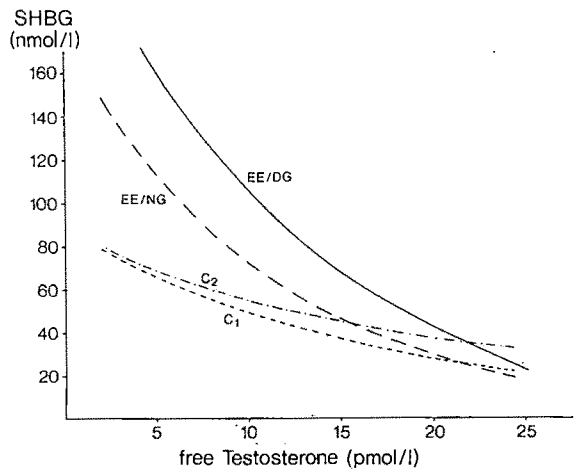

Fig. 3. Regression curves (second order) between the serum concentrations of SHBG and free testosterone (*EE/NG* = ethinyl estradiol–levonorgestrel; *EE/DG* = ethinyl estradiol–desogestrel; C_1 = control cycle; C_2 = washout cycle).

hydrotestosterone binding assay, rose from 24.3 ± 17.1 to 63.2 ± 37.5 nmol/L (+160%) during treatment with the triphasic ethinyl estradiol–levonorgestrel and to 105.0 ± 56.4 nmol/L (+330%) by the ethinyl estradiol–desogestrel combination (Fig. 2). The differences between the values of the control and treatment cycles and those between both preparations were significant.

When the free testosterone concentrations were measured directly, a significant suppression by 35% from an average of 9.37 ± 3.36 to 6.10 ± 3.35 pmol/L was found during treatment with both low-dose oral contraceptives (Fig. 1). Contrary to the effects on the concentrations and binding capacities of SHBG, there was no difference between the ethinyl estradiol–levonorgestrel and the ethinyl estradiol–desogestrel combination.

The discrepancy between the SHBG and the free testosterone levels became obvious when the regression curves (second order) were calculated from the corresponding values of the control, ethinyl estradiol–levonorgestrel, and ethinyl estradiol–desogestrel groups (Fig. 3). There was only a poor inverse correlation between the concentrations of SHBG and the free testosterone fraction, particularly at very high SHBG levels.

Comment

The present results show that treatment of women with the triphasic ethinyl estradiol–levonorgestrel preparation causes an elevation of SHBG levels by approximately 100%, while serum SHBG increased threefold to fourfold during the intake of the ethinyl estra- low-dose contraceptives suppressed the serum concen tration of total testosterone by 16%. Similar finding had been reported by several authors.[5-7, 11] The evalu ation of the free testosterone fraction by means of mea suring the SHBG binding capacity or by calculating th ratio of testosterone to SHBG, as carried out by mos investigators, would result in free testosterone level during treatment with ethinyl estradiol–levonorgestre that were twice those with ethinyl estradiol–desogestrel These calculated values, however, do not represen physiologic conditions, as some other steroid-bindin proteins are neglected. Those studies that had use more appropriate methods for the determination o free testosterone levels[5, 7, 11] did not compare the tw low-dose preparations.

Our results clearly demonstrate that the free testos terone fraction, as determined directly, is suppressed b both oral contraceptives to the same extent (−35%), al though the SHBG levels are much higher during treat ment with the ethinyl estradiol–desogestrel combina tion. When comparing the effects of two different con traceptive preparations Gaspard et al.[5] found that fre testosterone was decreased by 45% by both the triphasi ethinyl estradiol–levonorgestrel combination and by monophasic combination of 50 μg of ethinyl estradic and 250 μg of levonorgestrel, while SHBG was elevate (+85%) only by the former preparation. Mathur et al.[1] reported that apparent free testosterone concentra tions correlate with total testosterone levels but not wit SHBG. There are some indications that other bindin proteins, particularly albumin, may be involved to a higher degree than generally assumed. It was pointe out by Westphal[13] that the concept of the unbound ste roid hormone, as usually evaluated, is an oversimplifi cation. The hormone-protein interaction provides a dy namic binding system, involving association and disso ciation, and there are no static phases of bound an unbound steroid. According to the law of mass action the concentration of testosterone that is actually avail able is dependent not only on the binding constants bu also on the concentrations of the binding components.

It has been shown that the uptake of testosterone b target organs is considerably inhibited by both albumi and SHBG.[14] The uptake was in direct proportion t the free testosterone concentrations, which were simila in the presence of 90 μmol/L of human serum albumi and 90 nmol/L of SHBG. Moreover, it was demon strated that the effect of SHBG or albumin on the leve of free testosterone is more conspicuous at lower con centrations, while an increase above the normal rang of SHBG results only in minor alterations of unboun steroid. When the SHBG level was increased to mor than 50 nmol/L, the uptake of testosterone by the tissu

This was corroborated by studies of the effect of norgestrel on the binding of estradiol and testosterone to SHBG. When the serum level of SHBG was <50 nmol/L, the percent binding of the steroids was directly related to the SHBG concentration. However, when SHBG exceeded 50 nmol/L, the fractions of free steroids were independent of the serum level of SHBG but paralleled the total concentrations of testosterone and estradiol.[15] This corresponds to the present findings, as total and free testosterone levels were similarly depressed by both low-dose oral contraceptives, while the SHBG levels were raised excessively above the normal range to a different extent.

The reason for the decrease in the relative binding capacity of very high SHBG levels is unknown. It was, however, observed that the association constant of the albumin-testosterone complex decreases with increasing albumin concentrations, possibly because of protein-protein interactions.[13] The apparent binding affinity of cortisol to corticosteroid-binding globulin was also found to decrease with rising concentrations of the protein.[16] It is conceivable that similar interactions may affect the binding affinity of SHBG at high concentrations. It was demonstrated by Petra et al.[17] that the metabolic clearance rate of testosterone is inversely related to SHBG. The effect, however, is small, and is related to the distribution of testosterone bound between SHBG and albumin. There appears to exist an optimal upper level of SHBG in serum, and no matter how much more SHBG is circulating there will be little change in the metabolic clearance rate.

In women with androgenetic manifestations, an elevation of low SHBG levels may be followed by a decrease in free testosterone and an improvement of clinical symptoms. An excessive increase of SHBG above the normal range, however, does not seem to result in a further reduction of free testosterone, provided that total testosterone is normal. It appears to be of more clinical significance for women with hyperandrogenism that elevated levels of total testosterone are reduced by oral contraceptives. It is known that a pronounced increase in serum SHBG during treatment with hormonal contraceptives reflects a preponderance of the effect of the estrogen component. With respect to other possible side effects, a moderate change of estrogen-sensitive biochemical parameters seems to be more advantageous.

Source of prenatal care and infant birth weight: The case of a North Carolina county

Paul A. Buescher, Ph.D., Clinton Smith, M.D., M.P.H., Joseph L. Holliday, M.D., M.P.H., and Ronald H. Levine, M.D., M.P.H.

Raleigh, North Carolina, Nashville, Tennessee, and Greensboro, North Carolina

The impact of a comprehensive prenatal care program on the birth weights of infants born to low-income women is assessed. Women receiving care through the prenatal program of a large county public health department were compared to pregnant Medicaid-eligible women in the same county, who received prenatal care primarily from private-practice physicians. The percentage of low birth weight was 8.3 for the health department women compared with 19.3 for the Medicaid women. After differences between the two groups in race, marital status, participation in the Special Supplemental Food Program for Women, Infants, and Children (WIC), quantity of prenatal care, and other risk factors were statistically controlled, the chance of a Medicaid woman having a low-weight birth was still more than twice as great ($p = 0.007$). A case-management approach and greater use of services ancillary to basic obstetric medical care appear to contribute to the better birth weight outcomes in the health department. (Am J Obstet Gynecol 1987; 156:204-10.)

Key words: Prenatal care, low birth weight, Medicaid

It has been convincingly demonstrated that low birth weight greatly increases the risk of subsequent infant morbidity and mortality.[1, 2] Low birth weight also frequently results in higher medical care costs.[3] Thus the prevention of low birth weight has become a major concern of the health care community. Some of the more important factors shown to influence the risk of low birth weight are race, age, marital status, socioeconomic level, multiple birth, and prenatal care.[4]

The impact of prenatal care on birth weight has received considerable attention, in part because, among the major risk factors, prenatal care is probably the most amenable to change through deliberate health programs. Most studies of prenatal care and birth weight have looked at the quantity and timing of prenatal care, such as number of visits or month prenatal care began. More refined measures such as the Kessner Index consider number of visits and month care began in relation to length of gestation.[5] Such quantitative measures of care may be easily calculated from birth certificate data if the required components are recorded. Receiving much less attention, however, is how the scope and quality of prenatal care affect birth weight. The recent report by the Institute of Medicine on preventing low birth weight points to the need for more research on the content of prenatal care.[4]

A comprehensive prenatal care program for low-income women in 13 California counties resulted in significantly lower rates of low birth weight for these women in comparison with those in a matched control group of Medicaid women.[6] The present study looks at the effect of comprehensive prenatal care on the birth weights of infants born to low-income women in a North Carolina county. Women receiving prenatal care at the Guilford County Public Health Department are compared with Guilford County women on Medicaid, who received prenatal care mainly from private-practice physicians. It was hypothesized that the comprehensiveness of the health department's prenatal care program has a substantial positive impact on birth weights. If true, this would have important implications for provision of prenatal care to low-income women, where the problem of low birth weight is severe.

Material and methods

Guilford County, North Carolina, is a metropolitan area with a population of approximately 325,000. The county has a large and active public health department, with around 340 full-time-equivalent staff positions. Prenatal care is provided at two sites, in the cities of Greensboro and High Point. This project was initiated as a means of evaluating a health department program in terms of outcome (birth weight), rather than a "process" measure such as number of clients served. The

prenatal care program was chosen because it is one of the larger health department programs and because its outcome could be assessed with information from birth certificates. The results of this study turned out to have implications beyond the effectiveness of this particular health department program.

The first step was to indicate which of the 4037 Guilford County resident birth certificates for 1984 belonged to women who were in the prenatal care program of the health department. A list of the 426 women who received prenatal care at the health department and had a live birth in 1984 was provided by the health department and contained the name of each woman, the date of delivery, the date of her birth, and race. Computer and subsequent manual matching according to these variables resulted in successful identification of 396 birth certificates for babies born to health department women (a matching rate of 93%). Thus the "case" group became Guilford County residents who received prenatal care in this health department.

Guilford County women on Medicaid were chosen as a comparison group, primarily because they could be identified from Medicaid paid claims data. In Guilford County there is an agreement between the health department and the obstetricians that women who are eligible for Medicaid and then become pregnant will receive prenatal care through the private-practice physicians. The health department does not have the capacity to serve all indigent women in the county and its first responsibility is to the women with no insurance. Thus pregnant Medicaid-eligible women in this county are referred to the obstetricians' office-based practices by the health department or by the Department of Social Services. This type of arrangement may not exist in some counties in North Carolina, and indeed many Medicaid-eligible women in other areas do receive prenatal care from public health departments. It so happens, however, that in Guilford County the comparison of "health department" and "Medicaid" birth outcomes becomes essentially a comparison of public and private sources of care.

Like the women receiving prenatal care at the health department, the Medicaid-eligible women are predominantly poor and nonwhite. The income level for Medicaid eligibility is only one third to one half the poverty level in North Carolina, so this is a very low-income group of women that may differ in some ways from the health department women. A woman receiving prenatal care at the health department must be a resident of Guilford County and certified as having a family income of less than the poverty level. Potential problems of comparability between these two groups are considered later in this report.

In Guilford County most of the active obstetricians rotate hospital duty and thus the same physicians handle the deliveries of both the health department and Medicaid women. Therefore any differences in low birth weight between the two groups may be attributed mainly to differences in prenatal care rather than to differences in hospital management or intrapartum care.

Birth certificates for Medicaid women were identified by matching to Medicaid paid claims, with the use of name and age of mother. All 1984 inpatient hospital Medicaid claims for Guilford County residents with an ICD-9-CM diagnosis of 640-676 (conditions related to pregnancy and delivery) were selected, resulting in an unduplicated count of 556 women. Ninety percent (or 500) of these claims were successfully matched to birth certificates. It was expected that some of these claims would not match since some Medicaid hospital stays are for obstetric complications with no live birth occurring at the time. The matching indicated that 138 women were in both groups, that is, they received prenatal care at the health department and Medicaid paid for the hospital delivery. The health department and private-practice physicians have agreed that if a woman begins prenatal care at the health department and subsequently becomes eligible for Medicaid, she will complete her prenatal care at the health department for the sake of continuity, although at the time of delivery Medicaid would be available to pay for hospital charges. These women are counted in the health department group here since that is where prenatal care was received.

Besides the indicator of whether the woman received prenatal care in the health department or from a private-practice physician through Medicaid, most of the information used in this analysis is from the birth certificate: race, age, marital status, education, single or multiple birth, previous fetal death or death after live birth, birth weight, and quantity of prenatal care. The Kessner Index was used as an indicator of the quantitative adequacy of prenatal care. It considers number of visits and month care began in relation to length of gestation (see Table I for definition).* For purposes of this analysis, quantity of prenatal care was dichoto-

*Completed weeks of gestation, calculated from date of birth and date of last menstrual period on the birth certificate, was the only variable from the birth certificate used in this analysis that had more than a few missing values. Where only day of the month of date of last menstrual period was missing, the fifteenth was imputed. If calculated weeks of gestation was <18 or >48 for these live births, gestation was recoded to unknown. The calculated weeks of gestation was then compared with birth weight and, where the two were clearly incompatible, weeks of gestation was recoded to unknown. These procedures, plus the records with month or year of date of last menstrual period missing, resulted in about 2% of the births having unknown weeks of gestation and therefore unknown Kessner Index.

Table I. Criteria for adequacy-of-care index levels*

Adequacy of care	*Trimester of first prenatal visit*		*Gestation (wk)*		*No. of prenatal visits*
Adequate	First (1-3 mo)	and	18-21	and	≥3
			22-25	and	≥4
			26-29	and	≥5
			30-31	and	≥6
			32-33	and	≥7
			34-35	and	≥8
			≥36	and	≥9
Inadequate	Third (7-9 mo)	or	18-21	and	0 or not stated
			22-29	and	≤1 or not stated
			30-31	and	≤2 or not stated
			32-33	and	≤3 or not stated
			≥34	and	≤4 or not stated
Intermediate	All other combinations				

The index was treated as missing if a component was missing or if calculated weeks of gestation for the live birth was <18 or >48.

Table II. Live births in 1984 to residents of Guilford County, North Carolina, by source of prenatal care, birth weight, and selected risk factors for low birth weight

	Source of prenatal care		
	Public health department	*Private practice physician through Medicaid*	*All other*
No. of births	396	362	3279
<2500 gm (%)	8.3	19.3	7.1
Nonwhite (%)	65.4	81.5	25.2
Unmarried (%)	60.6	86.7	12.5
Age under 18 (%)	17.2	13.5	4.2
Education <12 yr (%)	47.8	45.6	14.9
Multiple birth (%)	2.8	3.9	1.9
Previous fetal death or death after live birth (%)	20.2	24.3	20.3
Not on WIC (%)	22.5	55.5	94.4
Prenatal care not adequate in quantity (Kessner Index) (%)	44.0	38.2	14.2

mized into adequate ("adequate" index) or not adequate ("intermediate" or "inadequate" index).

In addition to the information from the birth certificate, an indicator of whether the woman participated in the Special Supplemental Food Program for Women, Infants, and Children (WIC) before delivery was added. This was done by selecting Guilford County residents from a file of WIC women having a live birth in 1984 and matching on name and date of delivery. Out of 687 WIC records for Guilford County residents, 650 or 95% were matched with a 1984 Guilford County birth certificate.

The main analytical tool used here to address the question of the effect of source of prenatal care on birth weight among low-income women was logistic regression. An indicator (1 or 0) of whether the birth was low weight (<2500 gm) was used as the outcome measure. In assessing the effect of source of prenatal care on birth weight, it was necessary to control for other important influences on birth weight, for example, race, marital status, and quantity of prenatal care. The usual regression techniques are not appropriate when the dependent variable is dichotomous. Using logistic regression allows assessment of how source of prenatal care affects the odds of having a low-weight birth, after other important influences are controlled.

Results

Table II describes 1984 live births to Guilford County residents in terms of source of prenatal care, birth weight, and selected risk factors for low birth weight. Health department women and Medicaid women accounted for 9.8% and 9.0%, respectively, of 1984 Guilford county resident births. Women in these two groups

were much more likely than other Guilford County women to be nonwhite, unmarried, under age 18, of low education, and on WIC and to have had prenatal care that was not adequate in quantity. In a comparison of the Medicaid and health department groups, the Medicaid women were considerably more likely to be nonwhite, unmarried, and not on WIC. Since most Medicaid women qualified in 1984 through the Aid to Families with Dependent Children (AFDC) program, which mainly provides support to single-parent households, the very high proportion of the women that were unmarried is understandable.

The difference between the Medicaid and health department women in percentage of births that were low weight, 19.3 versus 8.3, is dramatic. (This difference is statistically significant at much less than $p = 0.001$.) Perhaps most surprising is that the percentage of low-weight births among the health department women was only slightly higher than that for the "all other" group shown in Table II, in spite of this being a "high-risk" group. The health department women had better birth weight outcomes than the Medicaid women even though the quantity of prenatal care (in terms of number of visits and timing of care) received by these women was, on the average, lower than that for the Medicaid group. Further examination of the data revealed that the somewhat lower quantity of care received by the health department women was entirely a function of starting prenatal care after the first trimester, rather than having fewer visits once care was begun.

In order to conclude more definitely that the nature of the prenatal care provided in the health department contributes to this difference in low birth weight, it is necessary to control for differences between the two groups in other risk factors for low birth weight. Table III considers the results of a logistic regression model with low birth weight as the dependent variable. Only the health department and Medicaid births are included here ($N = 758$). It can be seen that even after differences between the health department and Medicaid women in race, marital status, WIC, quantity of prenatal care, and the other measured risk factors were controlled, a woman receiving prenatal care from a private-practice physician through Medicaid was on the average more than twice as likely to have a low-weight birth ($p = 0.007$). Reasons for this strong effect will be considered in the following section.

The strongest effect in the model is that of multiple birth. A woman with a nonsingleton birth was more than 18 times as likely to have a low-weight baby than a woman with a singleton birth, independent of all other factors. Not being on WIC independently increased the chances of having a low-weight birth by 60% among the low-income women in this study. This is further corroboration of the effectiveness of the WIC program in preventing low-weight births. The independent effect of race on low birth weight shown here is not highly significant ($p = 0.18$), but it should be remembered that these two groups of women are predominantly nonwhite, with much less variation in race than would be found among all the births of a county or state. Other characteristics with a strong, independent effect on the probability of a low-weight birth are being unmarried, age under 18, and having had a previous fetal death or death after a live birth.

Table III. Estimated relative odds of low birth weight with presence of selected risk factors* (1984 Guilford County Health Department and Medicaid births, N = 758)

Risk factor	*Relative odds*	*p*
Nonwhite	1.58	0.18
Unmarried	1.80	0.11
Age under 18	1.92	0.06
Education <12 yr	.86	.57
Multiple birth	18.60	<.0001
Previous fetal death or death after live birth	1.94	0.01
Not on WIC	1.60	0.06
Prenatal care not adequate (quantity)	1.37	0.18
Medicaid provider of care (versus Health Dept.)	2.08	0.007

*These odds are derived from a logistic regression model and refer to the relative likelihood of a woman with the characteristic delivery of a low-weight baby compared with a woman without the characteristic. These are independent effects, that is, after the effects of all other variables in the model are controlled. The p values refer to the probability that this effect is due to random variation, given the sample size (758) and relative frequency of the variable (1 or 0). The model likelihood ratio χ^2 for testing the joint significance of all variables in the model is 78.82 with 9 degrees of freedom, $p < 0.01$.

Comment

Most evaluations of the effect of prenatal care on birth outcome have looked at the quantity of care in terms of the month of pregnancy in which care began and total number of prenatal visits. Indeed, these are the variables most likely to be recorded on birth certificates, and measures of content or quality are much harder to obtain. In the present study, the health department women actually had a lower quantity of prenatal care, on the average, than the Medicaid women, while having much better birth weight outcomes. Thus, if consideration of prenatal care had been limited to the Kessner Index or other quantitative measures of care, little effect on low birth weight would have been shown among these low-income women. Examining the nature and content of the prenatal care provided by the health department may provide insight concerning this differential.

The Guilford County health department provides a

comprehensive, coordinated system of prenatal care with extensive written protocols. Each woman is evaluated on entry and an individual prenatal care plan is developed. Special provisions are made to screen and educate the women about preventing preterm labor. The highest-risk women are referred to a high-risk maternity clinic at Moses Cone Hospital, a tertiary care center. Health education, counseling, and other health department services are also provided for these women. The women at nutritional risk are referred to the WIC program, which is administered through the health department. This link with WIC is very important, and Table II reveals that nearly 80% of the health department women are on WIC compared with less than half of the Medicaid women. Table III indicates that WIC does have a significant, positive, and independent impact on birth weight in this county. Higher participation in WIC could in fact be considered as one quality of the health department prenatal care program since referral is routine. It appears that the case management and coordination of services provided by the health department are very beneficial and that possibly the Medicaid women in Guilford County are much less likely to benefit from such an approach.

Other studies have also shown the advantages of a comprehensive, coordinated approach to prenatal care, particularly for high-risk, indigent women. Sokol et al.[7] evaluated a comprehensive prenatal care project in Cleveland and found that women on the program had significantly lower perinatal mortality and higher birth weights than women in a comparison group. They concluded that the major difference in prenatal care was in the ancillary services of the project, including nonmedical services such as patient education, home visitation, nutrition assessment and counseling, and social service assessment and intervention. The present study, which goes further to incorporate multivariate adjustments for group differences, strongly supports this perspective. Starfield's review of the literature[8] points to the inability of studies to consistently demonstrate that the amount of prenatal care alone influences the frequency of low birth weight and concludes that the scope and content of care are most important, particularly for high-risk populations. The Institute of Medicine's report on preventing low birth weight indicates that successful prenatal care projects frequently offer a "package" of services including outreach, counseling, and other nonmedical services. Certain populations, especially the poor and very young, "may be better served by public facilities offering a range of services than by physicians in private practice, who traditionally provide only medical care."[4]

One aspect of the Guilford County health department's prenatal care program that may contribute to its better birth weight outcomes, compared with those of the Medicaid women, is the heavy reliance on nurse practitioners for the provision of prenatal care. Sever nurse practitioners in the health department provide the first-line, ongoing care and communication, with specific problems or complications referred to physicians. The Institute of Medicine's report[4] suggests that these providers tend to relate to their patients in a nonauthoritarian manner and to emphasize education support, and patient satisfaction. They are likely to spend more time per visit with their patients than are office-based physicians, and women served by nurse-midwives and practitioners are more likely to keep appointments for prenatal care and to follow specified treatment regimens. In Guilford County, missed visits at the health department are followed by telephone calls, or home visits if necessary.

The follow-up, education, and linkage to other programs found in this health department would probably be less important for a group of highly educated and motivated pregnant women, but they appear to make a great difference for poor pregnant women in Guilford County. Peoples and Siegel[9] concluded that a comprehensive maternity and infant care (MIC) project in North Carolina had the most benefit for those mothers and infants at very high risk. As further indication that the benefits of comprehensive prenatal care are greatest for the highest risk women, the data for this study revealed a strong interaction between source of prenatal care and quantitative adequacy of care. The difference in low birth weight percent between the health department and Medicaid women was predominantly among those women not having an adequate quantity of prenatal care. The logistic regression analysis showed that, with other differences controlled, the risk of low birth weight was 4.5 times greater for the Medicaid women than for the health department women among those not receiving an adequate quantity of prenatal care ($p = 0.001$). For those women whose care was quantitatively adequate, however, the relative risk for the Medicaid women was only 1.2 and not significant ($p = 0.59$). Thus the ancillary services of the health department program appear to be most beneficial among those women who start prenatal care late or have an insufficient number of visits.

Any retrospective study, where random assignment to a "case" and "control" group is not possible, is subject to selection bias. Though the educational levels of the Medicaid and health department women were very similar (Table II), there was no information on income in the present study to use as a control. Since the income cutoff for Medicaid in North Carolina is extremely low it is likely that the Medicaid women in this study were on the average, poorer than the health department women. There could be substantial differences between the health department and Medicaid women on med-

ical complications of pregnancy, social and occupational stress, substance abuse, or other factors that affect birth weight and have not been measured or controlled for in this study. Another possible source of bias is that some women are eligible for Medicaid because they are "medically needy," which usually means that because of previous medical expenses they "spend down" to the Medicaid income level. Thus some of these women could be on Medicaid because of prior health problems. These potential biases could explain part of the much lower birth weights among the Medicaid women, but it is highly unlikely that their control would account for all of the differential. A look at the subset of 138 women who received prenatal care at the health department but qualified for Medicaid before delivery suggests that it is the prenatal care program of the health department, rather than unmeasured differences between the health department and Medicaid women, that accounts for a large part of the birth weight differential. Like the Medicaid women receiving care from private physicians, these 138 women were largely nonwhite and unmarried, yet their percent of low birth weight was 9.4 compared with 19.3 for the other Medicaid women. A logistic regression model for these two groups (N = 500), with the use of the same control variables as in Table III, indicated that the risk of low birth weight was 2.0 times as great for the Medicaid women receiving care in the private sector compared with the 138 women receiving prenatal care at the health department and later being certified for Medicaid ($p = 0.07$).

One possible contribution to the better birth weight outcomes among the health department women is that referrals are made to a high-risk prenatal care clinic at Moses Cone Hospital in Greensboro for women determined to be at risk of preterm labor. Of the 396 women in the health department prenatal care program, about 20% received at least part of their prenatal care at this high-risk hospital clinic. It is not known how many of the Medicaid women were referred to this clinic, although they would be eligible if determined to be at risk for preterm labor. Like referral to WIC, however, the formal linkage to this clinic should be considered a benefit of receiving prenatal care at the health department and not as a "bias" when comparisons are made with the Medicaid group.

A significant finding of this study is that the success of the Guilford County health department's program in preventing low birth weight was almost entirely through reducing preterm births rather than through reducing the incidence of intrauterine growth retardation. The percent of total births that were term and low weight was nearly the same for the health department and Medicaid groups. Much of the positive effect of the health department prenatal care program was through lengthening gestation, a finding that has also been suggested by Showstack et al.[10]

We do not expect that the Guilford County health department is typical in North Carolina in terms of its prenatal care program and it would be desirable to replicate and expand this type of study. In other areas, Medicaid women receiving prenatal care in the health department could be compared with Medicaid women receiving care in private settings, eliminating some of the comparability problems of the present study. It is now possible to match the Medicaid and WIC records to birth certificates on a statewide basis for North Carolina and we hope in time to identify women receiving prenatal care in health departments by means of a statewide automated health services information system. In an expanded study it would be possible, in addition to seeing if the results shown here hold up in other years and geographic areas, to examine the impact of prenatal care on important subcategories of low birth weight, such as births <1500 gm. The numbers were not large enough in the present study to support a more refined analysis of birth weight.

In summary, for women in poverty, a coordinated, comprehensive approach to prenatal care is essential. While visits for obstetric medical care may alone be adequate for women with higher education and income, women with fewer resources need additional services such as health education, counseling, nutritional assessment, and outreach and follow-up. While the present study has been largely a comparison of prenatal care in public and private settings because of the arrangements in Guilford County, the larger issue is the contrast between comprehensive and "traditional" prenatal care. What seems to make the difference are the services that are added to obstetric medical care. Physicians are frequently not able to hire educators, nutritionists, and other providers of ancillary services for their office staffs. What is needed is a coordination of services to assure that low-income women do get access to these needed nonmedical components of prenatal care.

We appreciate the valuable assistance provided by Reva Phillips of the Guilford County Health Department and by J. Michael Bowling of the State Center for Health Statistics.

Hairy cell leukemia in pregnancy: A case report

J. Kell Williams, M.D.
Detroit, Michigan

Hairy cell leukemia (leukemic reticuloendotheliosis) is a rare disease. No previously reported cases in pregnancy could be found with the use of available computer-assisted medical literature search programs. The pregnancy was complicated by progressive thrombocytopenia, leukopenia, and anemia that did not improve with delivery. The deterioration was eventually abated by postpartum splenectomy. (Am J Obstet Gynecol 1987;156:210-1.)

Key words: Hairy cell leukemia, pregnancy

Hairy cell leukemia (leukemic reticuloendotheliosis) was first described as an independent clinical and pathologic entity in 1958.[1] It is a rare disease, predominantly of men over the age of 50. No previously reported cases of this form of leukemia in pregnancy could be found with the use of available computer-assisted medical literature search programs.

Case report

D. H., a 34-year-old white woman, gravida 4, para 0-0-3-0, was diagnosed as having hairy cell leukemia at 7 weeks' gestation. Significant past history includes three previous pregnancy losses. The first, which occurred 2 years previously, was a missed abortion at 15 weeks' gestation; the second was an incomplete abortion 1 year previously. Both required a curettage for therapy. Ten months after the second curettage, she was admitted in shock with a ruptured left tubal pregnancy. A salpingectomy was performed. "Low platelets and a low white count" were noted postoperatively and thought to be secondary to multiple transfusions.

The anemia, thrombocytopenia, and leukopenia persisted during the next 4 months. Hematology consultation was obtained. Bone marrow biopsy was reported as showing mononuclear cells with the characteristic cytoplasmic projections pathognomonic of hairy cell leukemia. Also documented was an intrauterine pregnancy of approximately 7 weeks' gestation. Consultation with the maternal-fetal medicine service was obtained.

Initial hematologic studies revealed a hemoglobin of 9.9 gm/dl, a platelet count of 120,000/mm^3, and a white blood cell count of 2100/mm^3. Corticosteroid therapy and/or splenectomy were contraindicated because of the pregnancy. The maternal blood type was A, Rh negative, with a negative antibody screen. Other than the hematologic abnormalities, no other prenatal complications developed. A screening ultrasound examination at 26 weeks' gestation documented normal fetal growth.

The platelet count gradually fell to 70,000/mm^3 at 24 weeks' gestation, 60,000/mm^3 at 28 weeks' gestation, 40,000/mm^3 at 35 weeks' gestation, and eventually 25,000/mm^3 at 37 weeks' gestation. Repeat antibody screen at 32 weeks' gestation had revealed anti-C antibody, with a saline titer of 1:1 and negative Coombs test. The white blood cell count remained in the 2100/mm^3 to 1700/mm^3 range. At 37 weeks, the patient was transfused with 6 units of single-donor platelets. The posttransfusion platelet count was 37,000/mm^3. Nonstress tests, begun at 32 weeks, had been reactive up

until 37 weeks. The nonreactive test at 37 weeks was followed by a suspicious contraction stress test. Induction of labor was begun with oxytocin. After 6 hours of contractions and no signs of fetal distress, the cervix remained undilated while the effacement progressed from 20% to 100%. Six more units of platelets were transfused. The patient had a mild hyperthermic reaction to the transfusion.

After a night's rest, a second day of induction of labor was begun. Two hours into the active phase, persistent late decelerations developed. Dilatation and station did not allow for fetal scalp blood evaluation. A cesarean section was decided on and 1 gm of hydrocortisone was given intravenously. The immediate preoperative hemoglobin was 8.0 gm/dl, the white blood cell count was 1100/mm^3, and the platelet count was 40,000/mm^3. A female infant, weighing 2948 gm, was delivered by low transverse cesarean section with Apgar scores of 7 and 8. Ten more units of platelets and two units of whole blood were transfused intraoperatively. There was no clinical evidence of clotting abnormalities during the operation. The newborn infant had no neonatal complications.

In the recovery room, the patient became short of breath with wet rales throughout all lung fields. Immediate chest x-ray film was consistent with pulmonary edema, likely contributed to by the choice of whole blood for intraoperative transfusion. The patient responded rapidly to the intravenous administration of furosemide (40 mg). Postoperative hemoglobin was 7.9 gm/dl, white blood cell count was 7900/mm^3, and platelet count was 50,000/mm^3. Postpartum antibody screen revealed anti-C, anti-D, anti-CD, and anti-Fya (Duffy). Rh-immune prophylaxis was not indicated.

Moderate thrombocytopenia and leukopenia persisted and a therapeutic splenectomy was performed 5 weeks post partum. Hematologic status improved considerably and has been stable for 18 months.

Comment

Hairy cell leukemia makes up approximately 2% of all cases of leukemia. It is a neoplasia of B lymphocytes, although rare examples of T-lymphocytic forms have been described. There is a strong male predominance with a median age of 55. Presenting symptoms are usually weakness, fatigue, and easy bruising associated with pancytopenia. Classic symptoms of malignant lymphomas (weight loss, night sweats, fever) are present in less than 25% of cases. Approximately 10% of cases are discovered as incidental findings, as in this report. Splenomegaly, not initially noted in this patient, is found in more than 90% of cases at the time of diagnosis. Notably, there is an absence of adenopathy. The course of the disease is usually chronic. The average survival is 6 years, with a 51% actuarial survival at 4 years. The most common cause of death is infection. There are two reported cases of death from massive hemorrhage secondary to splenic rupture and one case of death secondary to hemorrhage into the lung. Splenectomy, with or without chemotherapy, is the treatment of choice with 92% of patients showing improvement of thrombocytopenia.[1,2] More recently, interferon therapy has been shown to have beneficial effects when splenectomy fails to achieve a response.[3]

This report represents a case of hairy cell leukemia in pregnancy. No previous cases could be found by computer-assisted literature search. The diagnosis was made in early pregnancy, before recognition of the gestation. The hematologic status of the patient gradually deteriorated throughout the pregnancy and was not improved with delivery. The deterioration has been abated to date by therapeutic splenectomy.

Multiple colposcopic biopsy specimens were collected from 160 women, with sampling of principal cervical and vulvar lesions as well as secondary areas of either minor acetowhitening or normal epitheluim. Papillomaviral deoxyribonucleic acid was detected by Southern blot hybridization in 197 (90%) of the 218 principal biopsy specimens and 93 (46%) of 198 secondary biopsy specimens. Although different papillomaviruses were found at different sites in 31 women, only six of 416 specimens contained multiple types within the same sample. Specific viral types were associated with specific disease patterns. Only one of 80 type 6 or 11 infections had a diagnosis greater than cervical intraepithelial neoplasia, grade 2. In contrast, 42 of 48 (90%) biopsy specimens of cervical intraepithelial neoplasia, grade 3, or invasive cancer contained type 16, 18, or 31. Nonetheless, 12 of 124 (10%) cases of condyloma and cervical intraepithelial neoplasia, grade 1, were associated with types 16, 18, and 31 infections. Of 58 women with multicentric disease, 46 had positive hybridizations for both cervical and vulvar lesions (32 showing the same type in both samples and 14 showing different viruses). Differing patterns of papillomavirus-induced disease arise partly from the predilection of specific viral types for certain anatomic sites and partly through variations in host response. Detection of viral deoxyribonucleic acid in 46% of the secondary biopsy specimens suggests that disease expression may represent focal breakdown of host surveillance within a field of latent papillomaviral infection. (AM J OBSTET GYNECOL 1987;156:212-22.)

Key words: Papillomaviruses, sexually transmitted diseases, colposcopy, cervical intraepithelial neoplasia

The papillomaviruses are species-specific deoxyribonucleic acid (DNA) viruses that are widespread in nature, causing characteristic proliferations on epidermal and mucosal surfaces. Papillomaviruses are classified by species and further subdivided into specific types according to nucleotide sequence homology. Most papillomavirus-induced lesions are benign, presenting as either cutaneous warts or mucosal condylomas.[1] However, certain papillomaviral types are oncogenic in vivo and in vitro, and there is now a substantial chain of evidence implicating these agents in the etiology of cervical, vaginal, and vulvar malignancy.[2, 3] The human papillomaviruses comprise three clinicopathologic groups: cutaneotropic viruses found in immunologically normal individuals, cutaneotropic viruses causing epidermodysplasia verruciformis in immunodeficient patients, and mucosotropic viruses infecting the genital, oral, and respiratory mucosae.

Papillomaviruses have a relatively simple structure. All of the viral genetic information is contained within a small circular molecule of double-stranded DNA, having a length of 8000 nucleotide base pairs.[1] The target

cells for viral infection are believed to be the basal layer of the affected area of epidermis or mucosa, establishing a viral reservoir that progresses to active expression as progeny cells differentiate during their migration toward the epithelial surface. From the functional viewpoint, the viral genome is divided into "early" and "late" regions. Studies with bovine papillomavirus type 1 indicate that genes from the early region establish and maintain viral control over the infected cell and initiate viral DNA replication. Genes in the late region are involved in capsid protein synthesis and virion assembly.[1-4] Papillomaviruses are unique in that virion production is tied to the cellular events of squamous differentiation and keratinization. Undifferentiated neoplastic cells do not permit completion of the viral life cycle, displaying instead a nonproductive infection with few if any cells progressing to virion assembly. Malignant transformation may occur in such tissues.[5]

Some bovine papillomaviruses have been passaged through many generations of abortive infection in tissue culture, but it has not been possible to induce productive expression or useful cytopathic effect in vitro.[1-4] Viral particles and capsid proteins are sometimes detectable in vivo within benign productive infections, by electron microscopy or immunochemistry. However, viral particles and capsid proteins are rarely present within premalignant or invasive lesions.[5] Fortunately, the availability of radiolabeled viral nucleic acid probes, developed through advances in recombinant DNA technology, has now made it possible to detect papillomaviral genomic sequences within a high proportion of premalignant and malignant tissues. Initial studies showed that condylomas and minor dysplasias generally contained type 6 or 11, while type 16 or 18 was most often detected in high-grade premalignancies or invasive cancers.[6-8] Subsequently, a new papillomavirus called type 31 was detected in about 20% of cervical dysplasias and 5% of cervical cancers obtained from Washington, D. C.[10]

Despite the constancy of these generalizations, current understanding of the natural history of papillomaviral infection in the individual woman is obscured by the markedly different patterns of disease that result from apparently equivalent viral exposures. This study was undertaken in an attempt to clarify some of these basic clinicopathologic paradoxes.

Material and methods

Study design. Type-specific differences in anatomic distribution and pathologic severity of sexually transmitted papillomaviral infections were studied in 160 women seen prospectively between March 1983 and February 1986. Each directed biopsy specimen was collected from an area of uniform appearance, as guided by a previously described colposcopic index.[11]

For the first 85 patients, biopsy specimens were collected systematically from multiple sites within the lower genital tract and analyzed by Southern blot hybridization for types 6, 11, 16, 18, and 31 and unclassified papillomaviruses. Preliminary data analysis showed that there was sufficient information for statistical testing of these secondary biopsy specimens. However, because analysis of the principal biopsy specimens required subdivision into two anatomic sites, five pathologic grades, and seven virologic categories, larger numbers were needed to reach statistical significance. Fiscal constraints dictated that the biopsy protocol in the remaining 75 patients be restricted to sampling areas of obvious abnormality.

Subject material. The study population was drawn mainly from a consecutive series of patients referred to R. R. with either extensive condylomas or varying grades of cervical, vaginal, and vulvar neoplasia. In addition, six samples of invasive cervical cancer were provided by C. R. Stanhope from the Mayo Clinic, Rochester, Minnesota; five samples of invasive cervical or vulvar cancer were provided by A. I. Sherman of Sinai Hospital, Detroit, Michigan, and one case of invasive cancer of the vulva was provided by G. R. Phibbs of the Medical College of Ohio, Toledo, Ohio.

Patients fell within two broad groups: First, 84 women presenting with cervical or vaginal disease, generally detected by Papanicolaou smears (nine with condyloma; 11 with grade 1, 31 with grade 2, and 22 with grade 3 intraepithelial neoplasia; and 11 with invasive cancer). Second, there were 76 women presenting with vulvar disease (53 with vulvar condylomas, 18 with Bowenoid lesions, and five with invasive squamous cancers). Eighteen of the 84 women in the first group had concomitant vulvar lesions, and 40 of the 76 women in the second group had concomitant cervical lesions. Hence the total study material comprised 218 principal lesions collected from 160 women (124 cervical and 94 vulvar lesions).

For the first 85 patients, a systematic series of colposcopic biopsies was performed throughout the lower genital tract, with sampling of (1) the worst area of the presenting lesion, (2) any adjacent area of lesser-grade acetowhitening surrounding the worst area of the presenting lesion, (3) the worst area of any multicentric lesion (a vulvar lesion in a patient presenting with cervical disease, or vice versa), (4) any adjacent area of minor grade acetowhitening at this second site, (5) essentially normal vaginal epithelium (with sampling of any colposcopic "asperities," if present), and (6) in patients with vulvar disease, normal vulvar epithelium at the intended margin of laser ablation. Each biopsy was bisected, half being placed in formalin for paraffin embedding and standard histologic examination, while the other half was frozen at −70° C for virologic anal-

ysis. Each frozen sample was completely sectioned on a cryostat, such that multiple step sections were available as histologic controls, while the remaining slices were used for DNA analysis.

In the remaining 75 patients, less extensive sampling was performed, with biopsy of only the most severe areas of cervical or vulvar abnormality.

Histologic criteria. For study purposes, cervical or vulvar lesions were assigned within one of five grades, with the use of the following histologic criteria.

The term condyloma acuminatum was applied only to clinically visible exophytic papillomas showing a microscopic pattern of basal proliferation and koilocytosis within maturing surface layers. Macroscopically invisible lesions, recognizable colposcopically as an acetowhite reaction and showing the same histologic pattern as overt condylomas, were termed condyloma planum. Mild cytonuclear atypia, consistent with a diagnosis of very mild dysplasia, were often seen in both clinically apparent and subclinical lesions. The only difference between condyloma acuminatum and condyloma planum is that one is a macroscopically apparent papilloma while the other is an invisible epithelial proliferation recognizable only after soaking with acetic acid.[11] Preliminary statistical analysis indicated that both the papillary and the subclinical lesions showed the same type-specific viral associations. Hence, for subsequent analyses, both variants were grouped within a single category.

The diagnosis of cervical or vulvar intraepithelial neoplasia, grade 1, was reserved for epithelia in which the lower third was occupied by undifferentiated stem cells. Above the basal layer, surface differentiation was generally associated with koilocytotic atypia. A diagnosis of grade 1 intraepithelial neoplasia carried a connotation of sufficient cytonuclear atypia and architectural disorganization to justify categorization as a possible precursor. However, the distinction between condyloma versus grade 1 intraepithelial neoplasia was often difficult and subjective.

The category of cervical or vulvar intraepithelial neoplasia, grade 2, was reserved for architecturally disorganized epithelia, in which the basal two thirds was occupied by undifferentiated basal cells while those in the upper third displayed appreciable maturation. There was usually a clear distinction between grades 1 and 2, but considerable overlap sometimes existed between grades 2 and 3 intraepithelial neoplasias.

The diagnosis of grade 3 intraepithelial neoplasia was reserved for lesions displaying complete architectural disorganization, being composed of abnormal cells that showed minimal or absent surface differentiation. Invasive cancer was diagnosed according to standard criteria. Except for one case of microinvasion, all of these

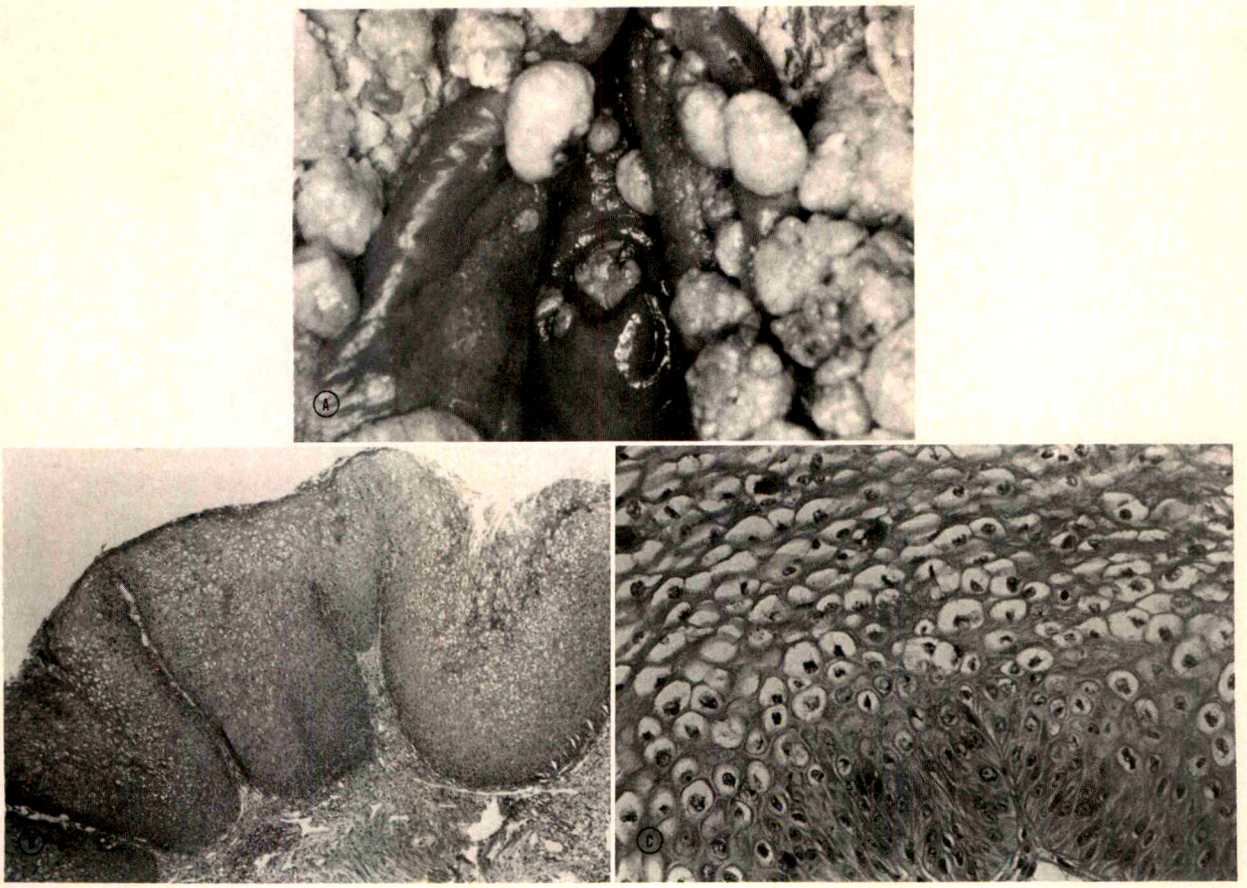

Fig. 1. Florid exophytic vulvar condylomas in an insulin-dependent diabetic patient, which were negative for papillomaviral DNA at hybridization. *A*: Colpophotograph. lesions were clinically overt malignancies treated by radical operations.

DNA hybridization. Samples were analyzed for viral DNA by Southern blot hybridization, as previously described.[10] For this procedure cellular DNA was extracted and reduced to small pieces by restriction enzyme digestion; the resulting fragments were separated according to size, by gel electrophoresis. The DNA fragments were denatured (meaning that double-stranded DNA was made single-stranded) and "blotted" onto a nitrocellulose filter. A panel of papillomaviral probes, each containing single-stranded, radiolabeled, type-specific viral DNA, was then incubated with the filter membrane under hybridization conditions, to allow annealing of the probes with any complementary segments of viral DNA present within the extracted cellular chromatin. The reaction was initially conducted under conditions of low stringency (meaning 35° C below the melting point of double-stranded DNA), to allow hybridization between any areas of partial nucleotide homology. After autoradiography, the filters were washed at high stringency (10° C below the duplex melting point of DNA) to destabilize any partial hybrids, such as those between the different papillomaviral types. The pattern of bands remaining on a second autoradiograph provided a sensitive and reliable guide to the type of any papillomaviral DNA present in the biopsy specimen. Results were then reconfirmed by high-stringency hybridization with probes derived from the individual papillomaviral types.

Data analysis. For each patient, the histologic grade and viral types of each of the multiple biopsy specimens were entered into a computerized data base and cross checked for accuracy. Data were analyzed on the Michigan Terminal System with the use of the Michigan Interactive Data Analysis System (MIDAS). This paper reports principally on the results of χ^2 testing of the associations between the major variables.

Results

Analysis of this data base revealed several relationships between viral type and either anatomic distribution or pathologic severity:

Papillomaviral DNA was detectable in the majority

Table III. Type-specific disease associations of the 94 principal vulvar biopsy specimens

Worst vulvar diagnosis	*HPV type in hybridization-positive biopsy specimens**						*HPV negative*	*Total*

of lesions at low stringency. Low-stringency hybridization showed that 194 (89%) of the 218 principal cervical or vulvar biopsy specimens contained papillomaviral DNA of one type or another. Apart from a slightly lower detection rate (79%) in minor cervical lesions, positive hybridization results in the other lesions approximated 90% (Table I). Within each diagnostic category, no obvious histologic differences were observed between biopsy specimens giving either positive or negative hybridizations, suggesting that some apparently negative biopsy specimens may represent infection by unclassified viral types that do not react with the existing panel of probes (Fig. 1).

Type-specific disease patterns detectable at high stringency. Highly significant relationships were observed between "low-risk" types and minor lesions and between "high-risk" types and malignant lesions (χ^2 = 81.9 and 115.3, p = 0.000). On the cervix, type 6 or 11 was found in 22 of 35 (63%) condylomas and six of 18 (33%) grade 1 intraepithelial neoplasias (Table II). On the vulva, "low-risk" viruses were detected in 53 of 68 (78%) exophytic condylomas and two of three grade 1 intraepithelial neoplasias (Table III). In contrast, "high-risk" viruses were found mainly within high-grade intraepithelial and invasive lesions (Tables II and III). Type 16, 18, or 31 DNA was identified in 20 of 22 (91%) biopsy specimens of cervical intraepithelial neoplasia, grade 3, and nine of 11 (82%) invasive cervical cancers (including the adenosquamous carcinoma shown in Fig. 2). On the vulva, type 16 was found in 15 of 18 (83%) high-grade intraepithelial neoplasias and four of five cancers (80%). Nonetheless, it is important to note that 13 of 124 (10%) principal biopsy specimens from minor cervical or vulvar lesions contained "high-risk" papillomaviral types (Tables II and III).

Anatomic distribution of the different papillomaviral types. When 197 virus-containing principal biopsy specimens are combined with 104 secondary biopsy specimens that did not duplicate the viral types found in the principal samples, it is seen that most of the papillomaviral types can infect any of the anatomic sites (Table IV). However, type-specific trends were apparent. Types 6 and 11 were found in 67% of 130 vulvar biopsy specimens but only 29% of 135 cervical samples. In contrast, types 16 and 18 were detected in 46% of cervical specimens versus 23% of vulvar specimens. The unclassified types were almost equally distributed among the three sites. Type 31 was found in 10% of the cervical dysplasias but was not encountered on the vulva (Fig. 3).

Multicentric lesions may show differing viral pat-

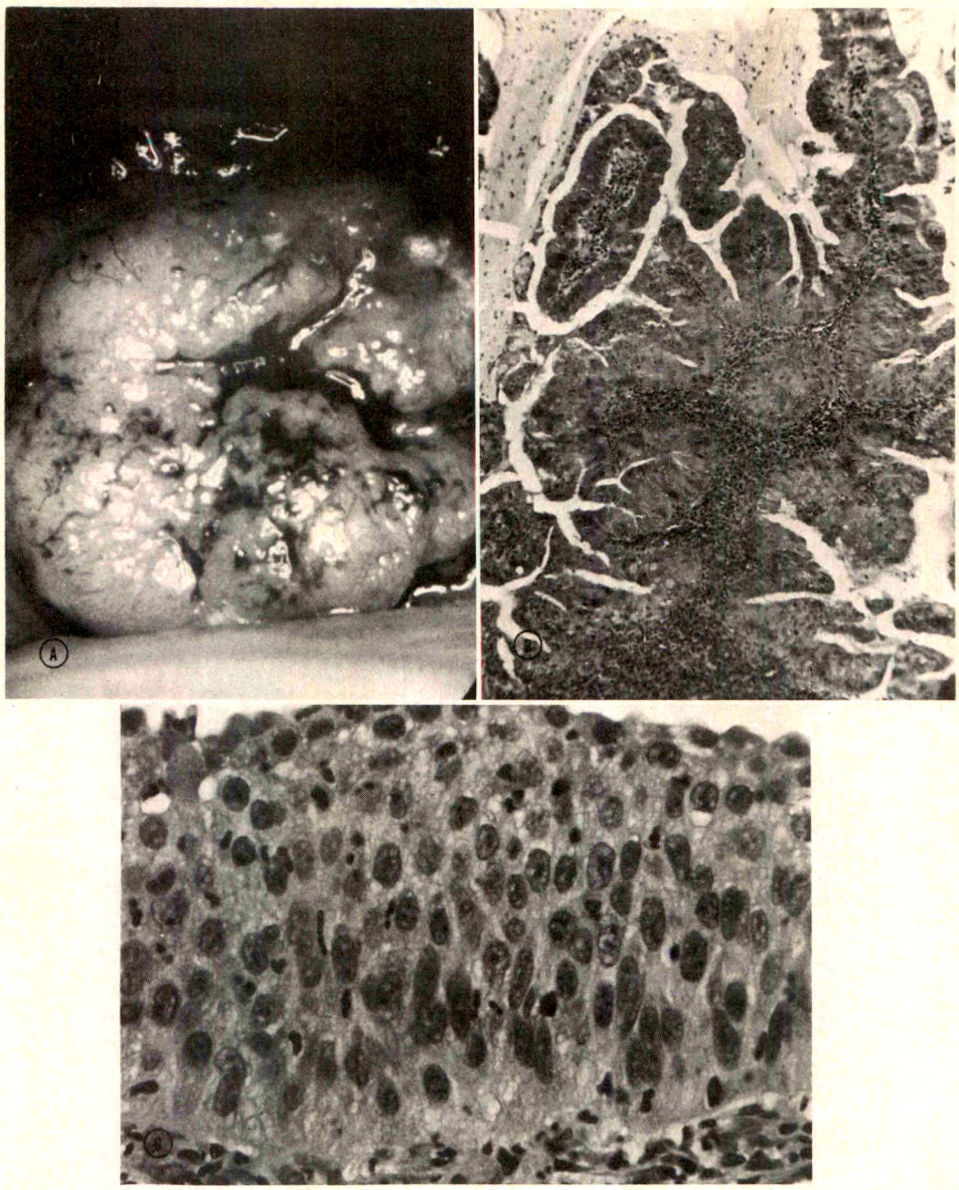

Fig. 2. A poorly differentiated adenosquamous carcinoma of the cervix that contained large amounts of papillomavirus type 18. *A*: Unmagnified photograph. *B*: Photomicrograph showing adenocarcinomatous element. terns. Among 58 women presenting with both cervical and vulvar disease, 46 had positive hybridization results at both sites. Thirty-two of these 46 samples (70%) had the same type of viral DNA in both samples and 14 (30%) showed different types (Table V). Multicentric lesions containing the same viral types tended to be of similar histologic grade. For example, 23 of 27 patients with minor lesions had the same papillomavirus within both samples, as did five of six patients with grade 2 or 3 intraepithelial neoplasia affecting both cervix and vulva. In contrast, only 43% of lesions containing different viruses were of similar histologic grade, with two, three, and four levels of disparity being found in 21%, 29%, and 7%, respectively (Fig. 4).

Infrequent occurrence of mixed papillomaviral infections. Although different papillomaviruses were frequently encountered at different sites within the same patient, it was uncommon to find more than one viral type within a single biopsy specimen. Multiple viral types were found at different sites in 30 women (14 principal biopsy specimens from women with multicentric lesions and 16 secondary biopsy specimens taken from women sampled according to the original protocol). In contrast, only six (2%) of 301 hybridiza-

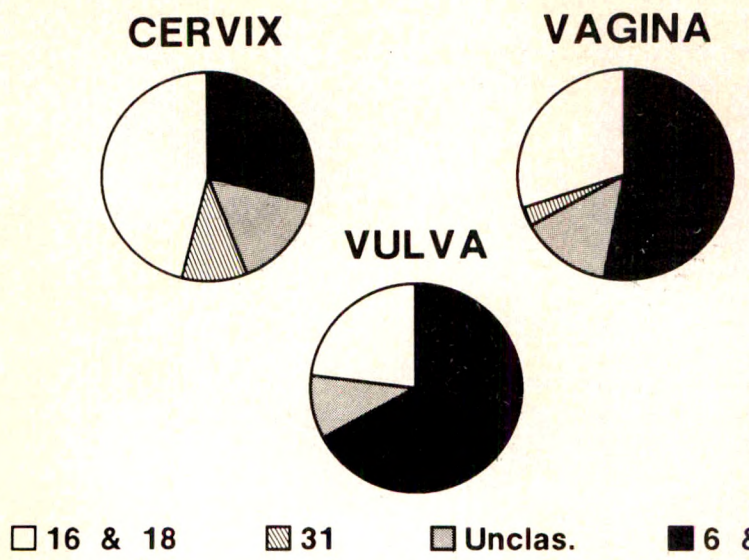

Fig. 3. A pie chart depicting the anatomic distribution of the different papillomaviral types.

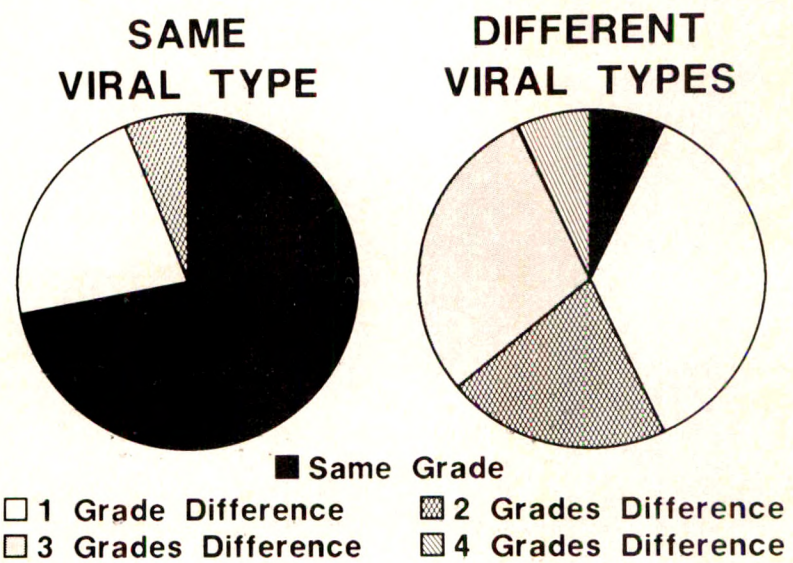

Fig. 4. A pie chart comparing histologic grades of cervical and vulvar lesions, according to whether both biopsy specimens contained the same type or different types of papillomaviral DNA.

tion-positive samples displayed more than one papillomaviral type within an area of uniform colposcopic appearance. Three of these six mixed infections, showing a combination of types 16 and 18, were obtained from histologically similar condylomas affecting the cervix, vagina, and vulva of the same patient (Fig. 5). A fourth example of mixed infection by types 16 and 18 was found within an area of minimally acanthotic vaginal epithelium, collected from a patient with type 6 associated cervical and vulvar condylomas. The two remaining examples were vulvar condylomas that contained a combination of type 16 plus type 6 or 11. Although these exophytic lesions were unremarkable from the clinical viewpoint, biopsy specimens from both patients showed foci of grade 2 intraepithelial neoplasia.

Latent papillomaviral infection in adjacent tissue. Latent papillomaviral infection was found in a substantial proportion of the histologically normal (or only minimally abnormal) secondary biopsy specimens. Detection rates at the various sites were as follows: 36 of 52 (69%) specimens from minor grade acetowhitening on the vulva; 16 of 25 (64%) areas of minor grade acetowhitening adjacent to more significant lesions

Table V. How multicentric lesions arise

Total	32	14	12	58

HPV = Human papillomavirus.

within the transformation zone; 34 of 80 (42%) specimens of vaginal epithelium showing a colposcopic pattern characterized by multiple, small acetowhite spikes ("asperities") projecting above an otherwise pink vaginal mucosa; two of eight (25%) specimens of normal-appearing immature squamous metaplasia, collected proximal to the new squamocolumnar junction in patients with cervical intraepithelial neoplasia containing type 16 or 18; and five of 33 (15%) specimens from normal-appearing skin at the intended margin of laser destruction (Table VI). Within each category, no histologic differences were observed between virus-positive and virus-negative samples.

The five patients who had viral DNA detectable in biopsy specimens of colposcopically normal vulvar skin had the most extensive disease, as reflected by the fact that all of the 18 additional principal or secondary biopsy specimens from these five women gave positive hybridization results. Two of these patients had immune deficiencies and two others had severe diabetes. Conversely, among the group in whom the samples of normal-appearing vulvar skin gave negative hybridization results, papillomaviral DNA was detectable in only 57 of the other 102 (56%) secondary biopsies collected from these women ($\chi^2 = 10.9$, $p = 0.001$).

Comment

Results of this study confirm that papillomaviral DNA (of one type or another) can be detected in most neoplastic lesions of the lower genital tract, irrespective of anatomic site or pathologic grade. Specific papillomaviruses were associated with specific disease patterns, suggesting that this relationship is causal rather than coincidental. For the purposes of examining broad differences in the biologic significance of the specific viral types, it is useful to combine both cervical and vulvar lesions into a single table. Grouping the principal cervical and vulvar biopsy specimens as benign to minimally atypical, partial thickness intraepithelial neoplasia, or fully neoplastic (with or without invasion) revealed that only one of 90 lesions (1%) containing type 6 or 11 had a diagnosis greater than grade 2 intraepithelial neoplasia (Table VII). Conversely, 38 of 70 samples (54%) containing type 16 or 18 DNA displayed an unequivocally malignant phenotype (Fig. 6). Type 31 and the unclassified group showed an intermediate pattern, being detectable in lesions that, on javerage, were significantly worse than those seen with types 6 and 11 but significantly less severe than those seen with types 16 and 18 ($\chi^2 = 1120.3$, $p = 0.001$).

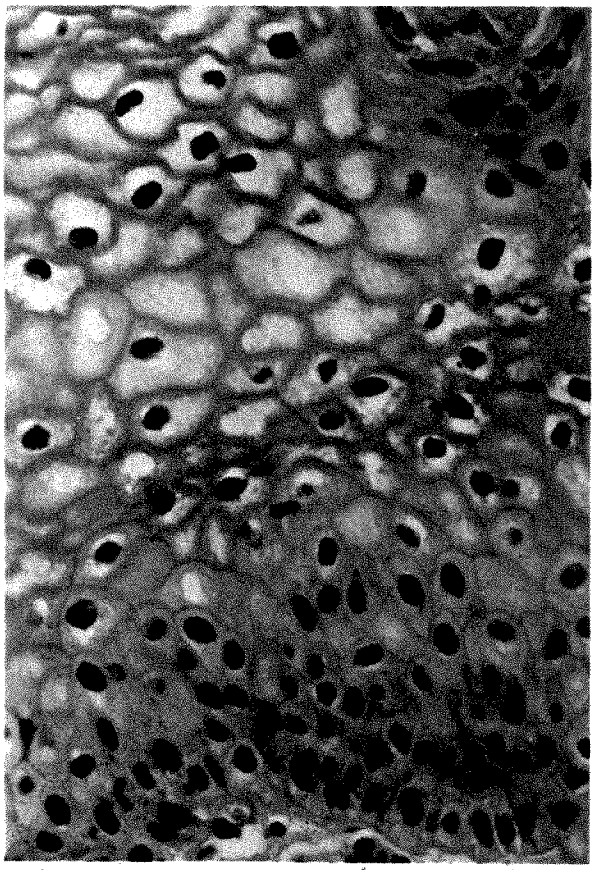

Fig. 5. A bland-appearing condyloma containing papillomaviral types 16 and 18. (Hematoxylin and eosin. Original magnification ×132.)

Events in the individual patient remain a mystery. Why the clinical consequences of papillomaviral infection should be generalized in some patients, yet localized to differing anatomic sites in others, is a major puzzle. The distribution patterns of the papillomaviruses detected in this study showed that the majority of types were detectable throughout the lower genital tract (Fig. 3). Nonetheless, type-specific differences in both site and severity were discernible. First, anatomic patterns showed some relationship to viral type. Whereas type 16 was detected in 36 of 71 high-grade cervical lesions and 20 of 26 vulvar neoplasias, type 31 was not found in any of 180 vulvar biopsy specimens and type 18 was not encountered among 26 vulvar

Table VI. Stepwise correlation between degree of pathologic expression and detectability of papillomaviral DNA

Biopsy category	*Biopsy site*	*Colposcopic appearance*	*Histologic features*	*HPV DNA detection rate (%)*
Principal, vulvar	Worst area of vulvar abnormality	Definite condylomatous or neoplastic lesion	Fully expressed koilocytotic atypia with or without neoplastic features	93
Principal, cervical	Worst area of cervical abnormality	Definite condylomatous or neoplastic lesion	Fully expressed koilocytotic atypia with or without neoplastic features	86
Secondary, vulvar lesion	Minor-grade acetowhitening of medial labia minora	Questionable lesion	Acanthosis, capillary proliferation, occasional vacuolated cells	69
Secondary, cervical lesion	Minor acetowhitening of cervical transformation zone	Questionable lesion	Acanthosis, capillary proliferation, occasional vacuolated cells	64
Secondary, vaginal walls	Vaginal epithelium, sampling of "asperities" if present	Questionable lesion	Acanthosis, capillary proliferation, occasional vacuolated cells	42
Secondary, normal metaplasia	Proximal to new squamocolumnar junction	Normal immature metaplasia	Normal immature metaplasia	25
Secondary, normal skin	Laser vulvectomy margin	Normal skin of labia majora	Normal skin	15

Table VII. Type-specific viral associations within the 218 principal biopsy specimens from cervix and vulva

Papillomaviral type	*Condylomas, CIN 1, and VIN 1*	*CIN 2 and VIN 2*	*CIN 3, VIN 3, and invasive cancer*	*Total*
No virus found	16	4	4	24
HPV 6 and 11	83	6	1	90
Unclassified HPV	13	9	1	23
HPV 31	2	5	4	11
HPV 16 and 18	10	22	38	70
Total	124	46	48	218

$\chi^2 = 120.3$, $p = 0.001$. CIN = Cervical intraepithelial neoplasia. VIN = Vulvar intraepithelial neoplasia. HPV = Human papillomavirus.

neoplasias. Second, the most florid manifestations of "low-risk" infections were seen on the introital mucosae or the labial and perineal skin, whereas the most severe effects of "high-risk" infections generally occurred on the cervix. For example, of 35 patients with type 6 or 11 lesions of the transformation zone, only 31% presented because of an abnormal Papanicolaou smear. The remainder were discovered during colposcopic examination of women seen for vulvar condylomas. Conversely, 93% of 58 women with type 16, 18, or 31 infections of the transformation zone presented with either abnormal cervical cytologic test results or symptomatic cancers. Hence individual variation in anatomic distribution and disease severity may be due, in part, to site-specific predilections of the different viral types.

Individual variations in anatomic extent and clinical course also appear to reflect profound differences in the effectiveness of host response. The detection of latent papillomaviral infections in 55% of secondary biopsy specimens collected from adjacent areas of minor grade acetowhitening and within 15% of colposcopically normal samples from the intended treatment margin indicates that viral genetic information is a necessary but not sufficient cause for condyloma formation or neoplastic change (Table VI). At least for the subset of patients in whom a single type of papillomaviral DNA was detectable at multiple sites, cell-virus interaction seems to be regulated by local factors. In short, does localized disease represent focal breakdown of host control within a field of diffuse papillomaviral infection?

Another puzzling feature of papillomaviral infection in the individual patient is the question of how multicentric disease arises. Of the 58 women with concurrent cervical and vulvar lesions, 32 arose through diffuse infection by a single viral type and 14 had multiple infections by two, three, or four papillomaviruses (Table V). Lesions of similar histologic grade generally contained the same virus, while those displaying marked disparity tended to show different types (Fig. 4). Nonetheless, reliable determination was not possible on clinical grounds.

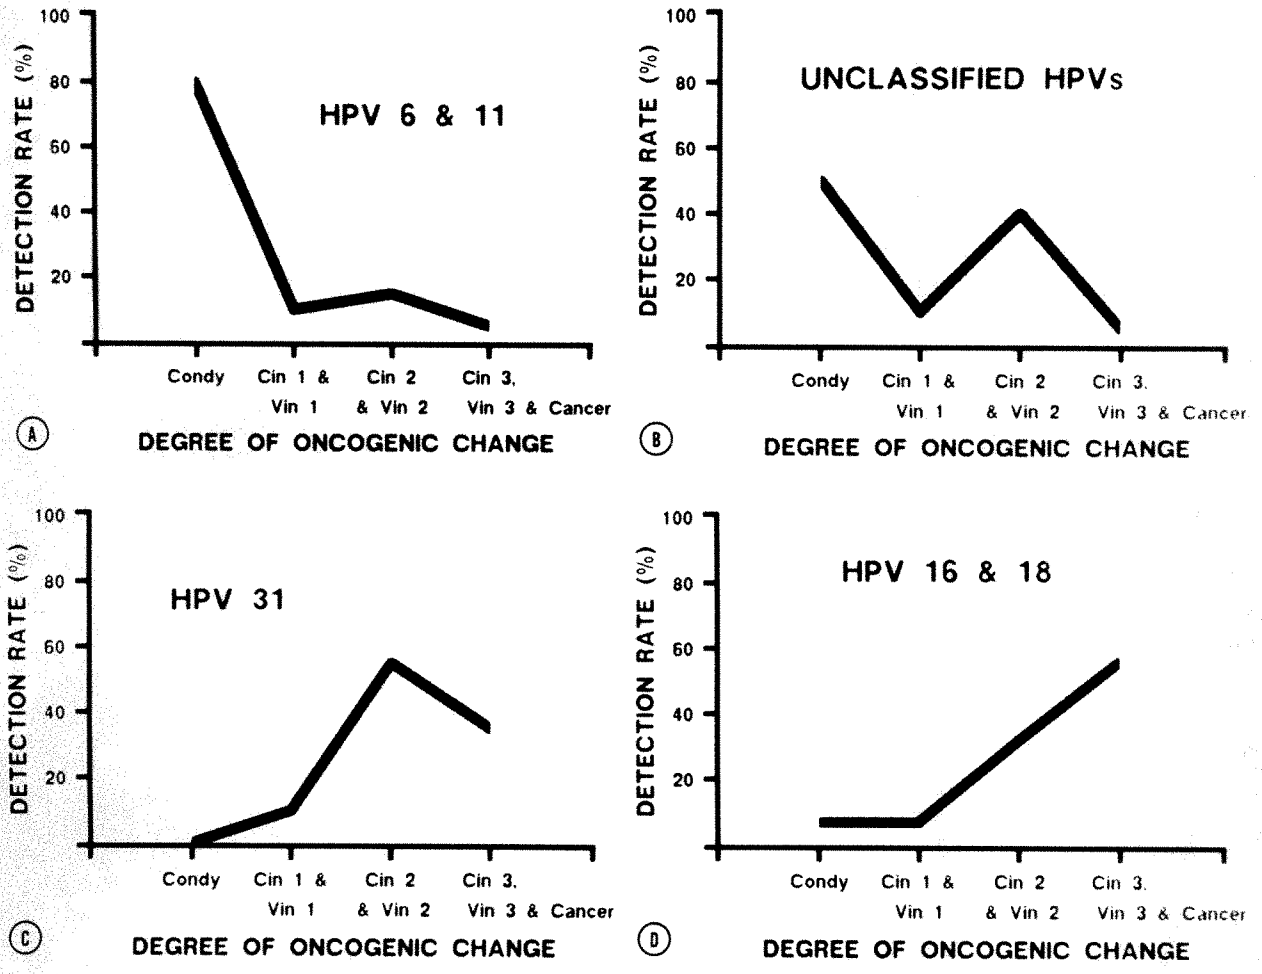

Fig. 6. A bar chart comparing the differing severities of histologic change associated with the different papillomaviral types. *A*: Human papillomavirus type 6 or 11. *B*: Unclassified types. *C*: Human papillomavirus type 31. *D*: Human papillomavirus type 16 or 18.

The fundamental reason for collecting multiple biopsy specimens from adjacent tissues was to test the hypothesis that preexisting type 6 or 11 infection might predispose to the subsequent entry of type 16, 18, or 31, thereby implicating the so-called "low-risk" types as facilitory factors. We found no evidence of any such relationship. Rather, when multiple papillomaviruses were isolated from a single patient, different types were generally confined to sharply demarcated areas of differing histologic appearance. In short, prior infection by one papillomavirus may actually resist subsequent superinfection by a second type. The only discernible relationship between the different groups appears to be that these various viruses display a morphologic resemblance and share a common mode of transmission.

Whether histologic examination can differentiate "high-risk" from "low-risk" disorders remains controversial. Some workers report that type 16–associated lesions are recognizable by the presence of atypical mitotic figures.[12] Others have emphasized that papillomaviral infection produces a spectrum of morphologic change, extending from condyloma to cancer.[13] Within this study, only one lesion having a diagnosis of severe dysplasia or worse was found to contain type 6 or 11 DNA. However, the converse was not true. Overemphasizing the association between the "high-risk" group and atypical mitotic figures would have led us to overlook the 10% of minor lesions associated with type 16, 18, or 31, including several bland-appearing overt condylomas (Fig. 5). Morphologic overlap was greatest in middle-grade lesions, as reflected by the detection of "high-risk" types in 59% and "low-risk" or unclassified types in 32% of grade 2 intraepithelial neoplasias (Table VII).

Treatment of vulvar condylomas should take account of the phases in the natural history of papillomaviral infection. Contact tracing studies suggested that, during an incubation period of 6 weeks to 8 months, latent viral infection becomes widely established within the lower genital tract.[14] Thereafter, rapid epithelial and capillary

proliferation often results in focal papilloma formation. For patients seen early in the active phase, the clinician should understand that much of the apparent "spread" of disease really represents differing rates of evolution from latent to active infection at different sites. After about 3 months, lesion growth generally slows, presumably as a result of the host immune response.[2] Although essentially all condylomas are surrounded by diffuse areas of subclinical infection, destruction of just the exophytic lesions will lead to stable remission in about 85% of women. Hence laser therapy should be reserved for women in whom lesions are too extensive for control by caustic agents and for those who do not respond to simpler therapies. Once the decision to use the laser has been made, it is difficult to see what is achieved by "spot welding" only the exophytic condylomas. Prior clinical studies[15] indicate that to avoid excessive rates of lesion recurrence, the approach should be to perform extended laser destruction, encompassing all areas of colposcopically suspected papillomaviral infection (as indicated by acetowhitening).

Opinion is divided as to the best strategy for managing cervical condylomas. Given the prevalence of "high-risk" types in condyloma planum, the susceptibility of metaplastic epithelium to malignant transformation, and the innocuous nature of outpatient therapies, there is much to commend a policy of treating all cervical lesions by transformation zone ablation.[16] While it is conceded that the majority of minor cervical lesions are not genuine precursors, effective treatment of all permissive infections would appear to be a reasonable step toward the control of western society's burgeoning epidemic of sexually transmitted papillomaviral infections.

In conclusion, a definite association was confirmed between papillomaviral type and pathologic grade. Types 6 and 11 were seldom found in bona fide neoplasias, whereas types 16, 18, and 31 were most commonly seen in cancers and definite premalignancies. Nonetheless, some 10% of clinically unremarkable lesions contained types 16, 18, and 31. There appeared to be a stepwise correlation between the degree of histologic disturbance and the frequency of positive hybridizations, papillomaviral DNA being detectable in 89% of the principal cervical and vulvar biopsy specimens (showing florid pathologic features), 55% of the minimally acetowhite secondary biopsy specimens (showing mild acanthosis, capillary proliferation, and occasional vacuolated cells) and 15% of the colposcopically normal secondary biopsy specimens (showing unremarkable vulvar skin or immature squamous metaplasia). It is postulated that individual variations in disease distribution and clinical course are explained partly by site-specific predilections of the particular viral types and partly by differences in host response. Given the chronicity of papillomaviral infections and the ease with which latent viral DNA can be detected in adjacent tissues, the major mechanism of treatment failure may be reexposure of the healing area to a viral reservoir in "normal" epithelium. Whether untreated male partners also contribute to this viral reservoir remains an open question.

We gratefully acknowledge Allison Quinn, B.S., Lai Lim, B.A., and Guy Campbell, M.S., for technical assistance, Harald zur Hausen, M.D., for making available several viral probes, and Robert Kurman, M.D., and Wayne Lancaster, Ph.D., for helpful consultation.

Yolk sac tumors of the ovary and the human yolk sac

In the present study a comparison was made between human yolk sacs and yolk sac tumors. Tubules surrounded by several to as many as 10 endodermal cells and intracellular tubules in one endodermal cell were frequently observed. The tubules were seen abundantly in the yolk sac of a 4-week pregnancy, and they resembled the reticular pattern of the yolk sac tumor. It was also observed that the papillary endoderm, which contained blood cells in the center and protruded into the endodermal tubules, resembled the Schiller-Duval body of yolk sac tumor. Ultrastructurally the tumor cells were similar to the yolk sac endoderm. α-Fetoprotein was positive in the yolk sac endoderm until approximately the seventh week of pregnancy. Yolk sac tumor was also α-fetoprotein–positive. In other words, our study of human yolk sacs of 4- to 11-week pregnancies presumes that the yolk sac tumor resembles the endoderm of 4- to 7-week pregnancies. (Am J Obstet Gynecol 1987;156:223-9.)

Key words: Yolk sac tumor, endodermal sinus tumor, human yolk sac

Schiller[1] reported on a tumor group with a specific histologic picture showing a glomerulus-like structure and termed the tumor "mesonephroma ovarii." Teilum[2] termed the tumor "endodermal sinus tumor" from the fact that the glomerulus-like structure resembles the endodermal sinus in the placenta of rats observed by Duval.[3] The theory of the histogenesis of the germ cell tumor proposed by Teilum has been supported, and the tumor has been termed "yolk sacs tumor" by Teilum et al.,[4, 5] and Huntington and Bullock.[6, 7]

A morphologic similarity of the yolk sac tumor to the human yolk sac has been pointed out.[8, 9] In the present study a morphologic comparison was made between the tumor and the human yolk sac in various stages of pregnancy, and in addition, a functional comparison of the producibility of α-fetoprotein was performed to study the histogenesis of the tumor.

Material and methods

We have seen 14 cases of yolk sac tumor in our department during the past 24 years. Light microscopic investigations were carried out on these 14 cases, seven of which were electron microscopically observed. After informed consent was received, the yolk sacs were obtained from pregnant patients who had undergone hysterectomies because of uterine myoma or cervical cancer and from those who had undergone elective abortion during the past 8 years. Yolk sacs were obtained from a total of 27 cases: one at pregnancy week 4, three at week 5, four at week 6, nine at week 7, five at week 8, two at week 9, two at week 10, and one at week 11.

For light microscopy the extirpated tissue fragments were fixed in 95% ethanol or 10% buffered formalin. Paraffin sections were treated with hematoxylin-eosin, Giemsa, or periodic acid–Schiff (PAS) staining. For electron microscopy, small pieces of tissue were fixed in 2.5% glutaraldehyde in 0.1 mol/L of cacodylate buffer, pH 7.4, for 1 hour and were postfixed in 0.2% osmium tetroxide in the same buffer for 1 hour. The samples were embedded in Epon 812 after dehydration in a graded ethanol series. Ultrathin sections were prepared with the aid of LKB 2088 Ultratome V and stained with uranyl acetate and lead citrate. Semithin sections adjacent to the electron microscopic sections were also prepared from the Epon-embedded material and stained with toluidine blue for light microscopic examinations. To investigate α-fetoprotein, the tissue fragments of the extirpated yolk sac tumors and the human yolk sacs were fixed in 95% alcohol. Paraffin sections were prepared and immunohistochemical localization of α-fetoprotein was carried out with use of the peroxidase antiperoxidase method.[10, 11] In addition, to confirm the specificity of α-fetoprotein, the cervix uteri, endometrium, and dysgerminoma were used as controls.

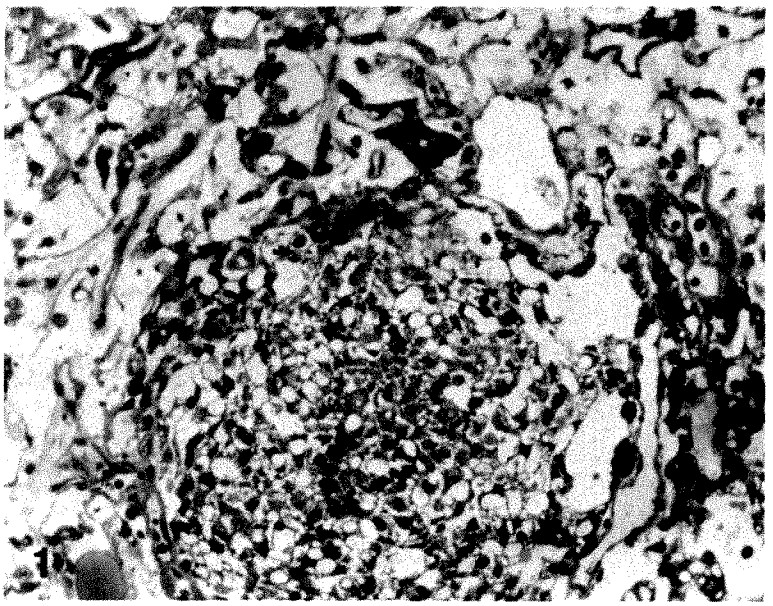

Fig. 1. Cystic and microcystic structures fused mutually and formed a reticular pattern (toluidine blue staining).

Results

Ovarian yolk sac tumor

Light microscopic findings. The highly atypical tumor cells showed various histologic structures that were characterized by a radiated arrangement of tumor cells centering around blood vessels. The structure resembled a glomerulus-like structure, and this was designated as an endodermal sinus pattern or a Schiller-Duval body. Around this structure, cystic and microcystic structures frequently were fused together, and a picture resembling a reticular pattern was seen (Fig. 1). Furthermore, undifferentiated small cells were closely arranged to form a solid pattern. Hyaline globules were seen intracellularly and extracellularly and were PAS stain–positive in resistance to diastase digestion. Amorphous substances having a similar stainable property were seen extracellularly. However, only a few parts of the polyvesicular vitelline pattern were observed. The other tumor components were complicated by dysgerminoma, cystic teratoma, and Brenner tumor in two, four, and one patients, respectively.

Electron microscopic findings. Cytoplasmic protrusions of tumor cells were seen between the vascular endothelial cells of the Schiller-Duval body and the tumor cell, and a basement-membranelike material having moderate electron density was seen around the protrusions. The adjacent tumor cells were bound by a tight junction and desmosomes. Short microvilli were observed on the cell surface and in the magnified intercellular cavity. The nucleus was elliptic or irregular in shape and had one to two nucleoli exhibiting nucleolonema. The cytoplasm was abundant in organelles, and many free ribosomes and glycogen granules were distributed all over the cytoplasm along with glycogen conglomerates at the border of the cytoplasm. Many ovoid mitochondria, closely related to the rough endoplasmic reticulum, were also noted.

Tumor cells forming structures other than that of the Schiller-Duval body consisted of similar cellular organelles and closely resembled the tumor cells forming the Schiller-Duval body; that is, the tumor cells were sparsely arranged, had cytoplasmic protrusions, and were bound by a tight junction and desmosomes. Microvilli were seen in the enlarged intercellular cavity and in the tubule in one tumor cell. The nucleus was large and irregular in shape and had well-defined nucleoli. Cellular organelles were abundant, and rough endoplasmic reticulum was arranged in a parallel manner and often surrounded by ovoid mitochondria, moreover, abundant rosettelike accumulations of glycogen granules were observed (Fig. 2). Occasionally a well-developed Golgi apparatus was seen, and in addition, ovoid amorphous substances having high electron density were observed near the rough endoplasmic reticulum. Extracellularly an amorphous substances surrounding the tumor cells was observed. This substance was the same as the basement-membranelike material seen in the Schiller-Duval body.

As mentioned previously, in light microscopic studies the tumor represented varying histologic pictures, but essentially it consisted of tumor cells having the same fundamental structure when viewed with an electron microscope.

Human yolk sac. A comparison of yolk sac tumor

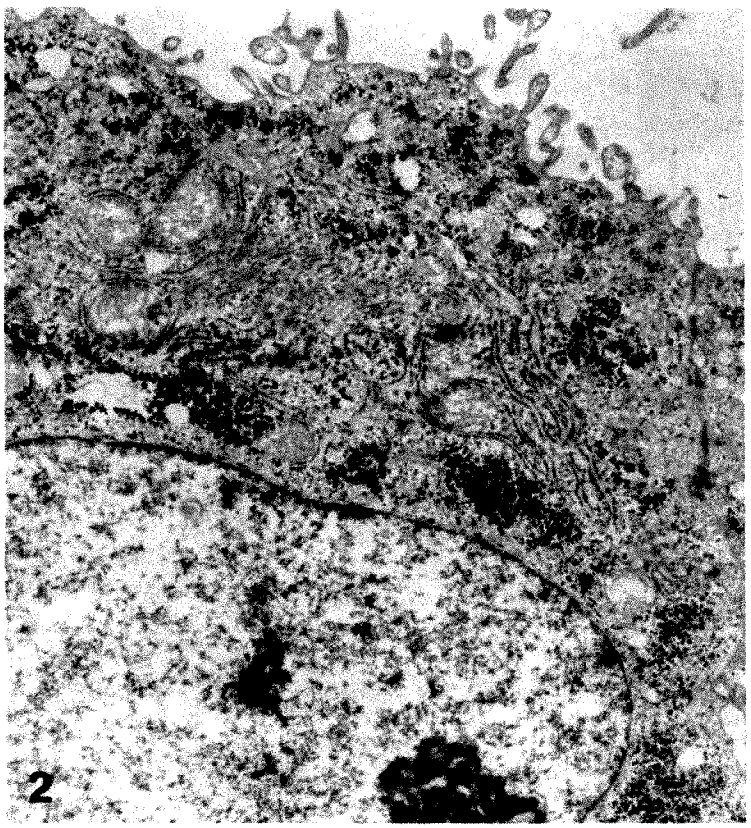

Fig. 2. A reticular pattern of tumor cells. Microvilli were seen on the cell surface. Desmosomes were seen. The nucleus had a nucleolus exhibiting nucleolonema. Ovoid mitochondria were closely in contact with parallelly arranged rough endoplasmic reticulum. Glycogen fields were observed as being dispersed. (× 10000.)

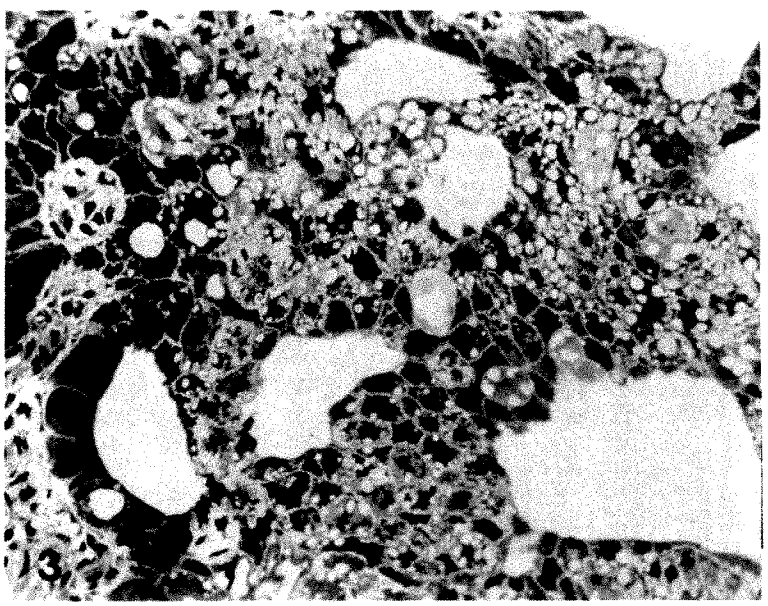

Fig. 3. Many endodermal tubules and intracellular tubules were seen in the endoderm layer (fourth week of pregnancy; toluidine blue staining).

Fig. 4. Blood cells with a large nucleus were observed in the center of the endoderm protruding into the endodermal tubule (sixth week of pregnancy; toluidine blue staining).

findings, mainly those of the yolk sac endoderm, was made.

Light microscopic findings. The human yolk sac wall consisted of three layers: an endoderm facing the yolk sac cavity, a mesothelium facing the chorionic cavity, and a mesenchyme situated between them. The endodermal cells were cuboidal and displayed a flagstone-like arrangement. Several to approximately 10 endodermal cells were arranged to form tubular structures (endodermal tubules), and a formation of microtubular structures also occurred within the cytoplasms of the endodermal cells (intracellular tubules). In the yolk sac of a 4-week pregnancy, many endodermal tubules and intracellular tubules were seen in the endodermal layer (Fig. 3). A structure in which the papillary endoderm protruded into the endodermal tubules was seen in some yolk sacs of 6- and 7-week pregnancies. Large blood cells were occasionally noted in the center of the papillary endoderm. This structure was found to be spherical when observed in the serial sections (Fig. 4). PAS staining after diastase digestion was positive until approximately the seventh week of pregnancy but negative thereafter.

Electron microscopic findings. Short microvilli were regularly arranged on the cell surface. Intercellularly, many slender cytoplasms protruded microvillously. The cells were bound by desmosomes and a tight junction. The nucleus was generally ovoid and possessed nucleoli exhibiting nucleolonema. The cytoplasm was abundant in organelles, and the rough endoplasmic reticulum showed several 10-layered parallel arrangements. Glycogen granules were abundant. The formation of a glycogen field and a rosette by glycogen granules were observed. Ovoid mitochondria were present in close contact with the rough endoplasmic reticulum. Free ribosomes and Golgi apparatus were also observed as being dispersed. On the cell surface facing the endodermal tubules or intracellular tubules, microvilli were seen (Fig. 5). A basement membrane was noted between the endoderm and mesenchyme in some yolk sacs of 6- and 7-week pregnancies (Fig. 6). A spherical amorphous substance with a high electron density was observed in the cytoplasm of endodermal cells until the fifth to ninth week of pregnancy (Fig. 5).

α-Fetoprotein findings. Of 14 patients with yolk sac tumor, preoperative α-fetoprotein values in six patients (whose serum α-fetoprotein was measured by radioimmunoassay) were all found to be positive. α-Fetoprotein values increased or decreased before and after surgery and at the time of chemotherapy as well as upon recurrence. A study of the immunohistochemical localization of α-fetoprotein produced negative results in the cervix uteri, endometrium, and dysgerminoma, which were selected as controls; α-fetoprotein, however, was positive in the tumor cells of the yolk sac tumors. In the human yolk sac, α-fetoprotein was positive in all the layers of the yolk sac endoderm until the seventh week of pregnancy (Fig. 7). There were α-fetoprotein–positive cases in some yolk sacs after 8 weeks of pregnancy. Neither the mesothelium nor the mesenchyme gave positive findings. These modes of appearance of α-fetoprotein were nearly coincident

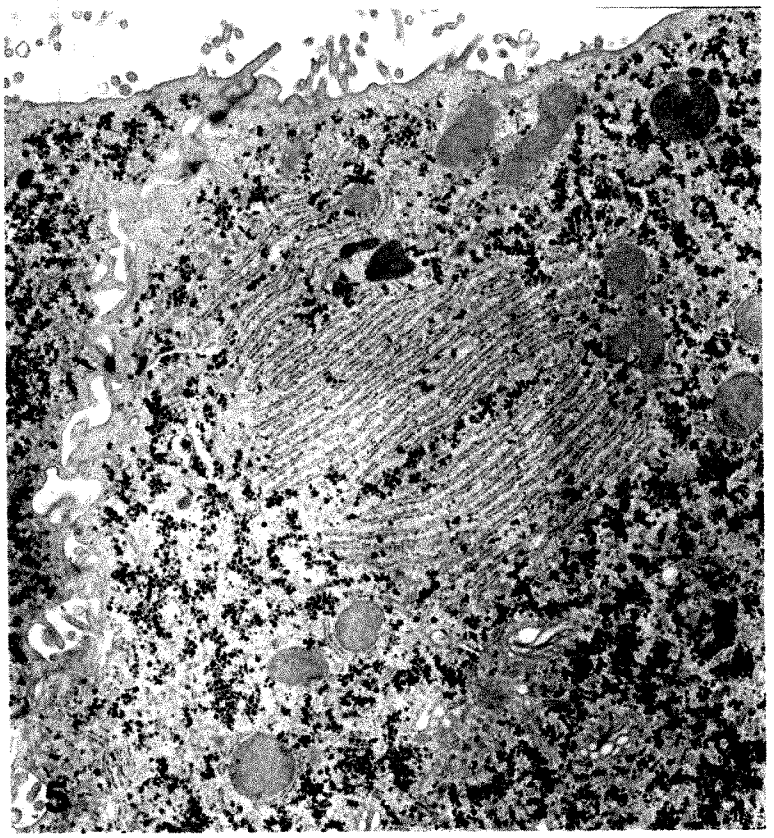

Fig. 5. Microvilli were seen on the cytoplasmic surface. Parallelly arranged rough endoplasmic reticulum was adjacent to mitochondria. Glycogen was abundant and distributed all over the cytoplasma. A spherical amorphous substance was seen near the rough endoplasmic reticulum (sixth week of pregnancy). (×5000.)

Fig. 6. Basement membrane was observed at the border between the superior endoderm and the inferior mesenchyme *(arrows)* (sixth week of pregnancy). (×16000.)

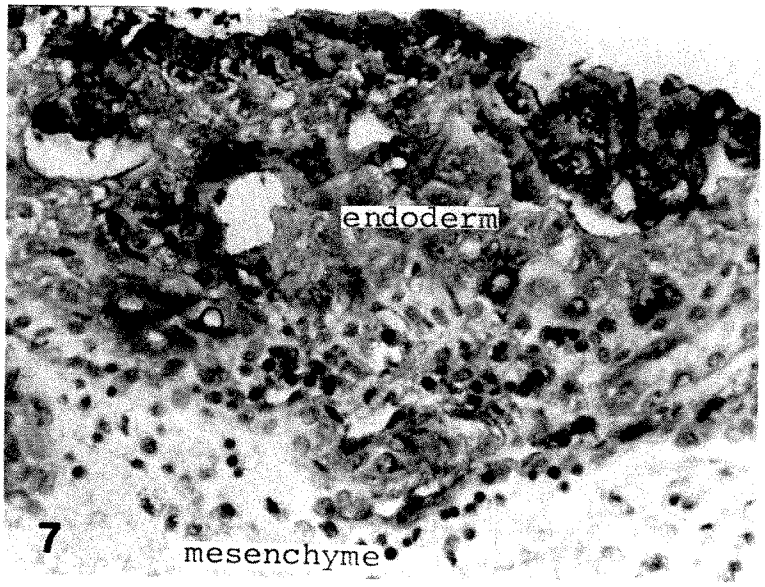

Fig. 7. α-Fetoprotein was observed as a brownish yellow granule in all the layers of the yolk sac *endoderm* of a 6-week pregnancy. *Mesenchyme* was α-fetoprotein–negative.

with those of the substance that was PAS stain–positive after diastase digestion.

Comment

With respect to the histogenesis of the yolk sac tumor, Teilum et al.[2, 4, 5] compared the histologic picture with viviparous tissue and proposed a histogenesis theory of the germ cell tumor. Huntington and Bullock[6, 7] supported Teilum's theory, and at present Teilum's theory is accepted as valid.

Despite the indication of morphologic similarity of the tumor to the human yolk sac, there have been few comparative studies of the tumor and the human yolk sac. In the report by Gonzalez-Crussi and Roth,[8] it is difficult to detect by light microscopy in the human yolk sac the structure of the placenta of rats for which the term "endodermal sinus tumor" was proposed by Teilum. This may be due to the insufficient number of cases used in previous reports and the fact that until now no studies on the yolk sac in various stages of pregnancy have appeared in the literature. However, our study of yolk sacs in 27 cases showed a similarity between the yolk sac endoderm and the yolk sac tumor. By light microscopy both gave positive results in PAS staining after diastase digestion, and they were also α-fetoprotein–positive. The findings of the endodermal tubules and intracellualr tubules seen in the yolk sac endoderm of the 4-week pregnancy cases resembled those of the reticular pattern of the tumor. The structure in which the papillary endoderm contained blood cells in the center and protruded into the endodermal tubules was spherical in the serial sections but closely resembled the Schiller-Duval body. Moreover, an electron microscopic comparison between the yolk sac tumor and the yolk sac endoderm showed morphologic similarities such as a mode of cellular bonding, microvilli, nucleoli-presenting nucleolonema, layered rough endoplasmic reticulum closely adjacent to mitochondria, rosette-forming glycogen, ovoid and amorphous granules, and basement membrane and basement membrane–like materials. As mentioned above, morphologically the tumor had a marked similarity to the yolk sac endoderm.

Gonzalez-Crussi and Roth[8] reported that the morphologic change began at the tenth week of pregnancy. However, in our study the morphologic findings and the functional study of α-fetoprotein production of the yolk sac suggest that activity is present until approximately the seventh week of pregnancy and declines toward degeneration and involution thereafter.

In respect to the basement membrane of the human yolk sac, both Hoyes[12] and Fukuda[13] have reported no observations of the basement membrane when the yolk sac was observed in the eighth and tenth week and in the fourth to fifth week of pregnancy, respectively. However, Nogales-Fernandez et al.[9] have mentioned that when the yolk sac was observed in the seventh and twelfth week, the basement membrane was seen between the endoderm and the mesenchyme in the yolk sac of a 7-week pregnancy, and its presence was the main characteristic of the young yolk sac. We also observed the basement membrane in the yolk sacs of 6- and 7-week pregnancies. This fact, as Nogales-Fernandez et al.[9] have indicated, suggests that the basement

membrane may be main characteristic of the young yolk sac. However, our observations of the yolk sacs of 4- and 5-week pregnancies showed the absence of the basement membrane, as was also reported by Fukuda.[13] These findings suggest that the basement membrane is observable during a certain period, that is, the period of greatest activity in the human yolk sac. The basement membrane is presumably a material such as α-fetoprotein produced in the yolk sac.

In a study of the yolk sac tumor, Abelev et al.[14] have suggested that the α-fetoprotein becomes one index of yolk sac tumors, including extragonadal ones, and Nogales-Fernandez et al.[9] have proved the production of α-fetoprotein by means of the tissue culture method. In our patients also the serum α-fetoprotein was positive, and furthermore, α-fetoprotein was proved to be present in the tumor cells. With regard to human yolk sacs, Gitlin et al.[15] have proved the production of α-fetoprotein by culturing human yolk sacs and reported that the production was especially conspicuous in young yolk sacs. Our demonstration of the localization of α-fetoprotein has disclosed that α-fetoprotein is positive in the yolk sac endoderm until the seventh week of pregnancy and that the production of α-fetoprotein is the most conspicuous in this period. Since this period is nearly coincident with the time of pregnancy at which the basement membrane was seen, the basement membrane presumably consists partly of α-fetoprotein. The electron microscopic findings of the endoderm exhibit vigorous protein synthesis, which supports these facts.

As mentioned above, in view of the morphologic and functional aspects of α-fetoprotein production, it was concluded that the tumor resembles the human yolk sac endoderm before 7 weeks of pregnancy.

Effects of maternal anemia on uteroplacental and fetal oxidative metabolism in sheep

Mary E. Paulone, M.D., Daniel I. Edelstone, M.D., and Ann Shedd, M.D.
Pittsburgh, Pennsylvania

We studied the effects of acute isovolemic maternal anemia on several variables of uterine and fetal oxygenation to answer these two questions: (1) Does maternal anemia cause reductions in oxygen delivery to the uterus, placenta, and fetus? (2) If so, what is the impact of such reductions on fetal oxidative metabolism? In 15 chronically catheterized pregnant sheep and fetal lambs, we measured uterine and umbilical blood flows and uterine and fetal oxygen deliveries, oxygen extractions, and oxygen consumptions at various, randomly selected maternal hematocrits ranging from 30% to 8%. We altered maternal hematocrit by performing isovolemic exchange transfusions with plasma or packed red blood cells. Uterine and umbilical blood flows were measured with the radionuclide-labeled microsphere technique, and the variables of oxygenation were calculated with modifications of the Fick principle. Decreases in maternal hematocrit led to linear reductions in oxygen delivery to the uterus, placenta, and fetus. Despite reductions in oxygen delivery of up to 50%, fetal oxygen consumption was maintained, because of compensatory increases in oxygen extraction. When hematocrit (and thus fetal oxygen delivery) was reduced by more than 50%, fetal oxygen consumption and the arterial blood base excess both decreased, indicating that, at these hematocrit levels, the supply of oxygen to fetal tissues was inadequate for the demands for oxygen by these tissues. (Am J Obstet Gynecol 1987;156:230-6.)

Key words: Uterine blood flow, umbilical blood flow, fetal oxygen consumption, acute isovolemic anemia

Anemia during pregnancy is a common clinical problem, affecting up to 5% of all pregnancies.[1] Anemic women are more likely to be delivered of infants who are stillborn or hypoxic at birth. Although the adverse consequences of maternal anemia have been known for many years, the specific reasons for these poor outcomes are unknown. During anemia the delivery of oxygen to the fetus may be reduced. The ways in which uteroplacental or fetal tissues could adjust to a reduced oxygen delivery should be the same as those by which tissues in nonpregnant animals compensate for anemia.[2] Although the cardiovascular effects of anemia on nonpregnant animals have been systematically studied,[2, 3] there are few experimental data on the circulatory consequences of anemia when it occurs during pregnancy.[4, 5] The purpose of our studies was to answer the following two questions: (1) Does maternal anemia cause reductions in oxygen supply to the uterus, placenta, and fetus? (2) If so, what is the impact of these reductions on fetal oxidative metabolism? To answer these questions, we have designed experiments in pregnant sheep to assess the effects of variations in maternal hematocrit on the oxygen tensions and oxygen concentrations of uterine and umbilical blood, the oxygen consumptions of the uterus and fetus, and the acid-base balance of fetal blood.

Methods

Preparation of animals. We surgically prepared 15 singleton pregnant sheep whose gestational ages ranged from 105 to 130 days (term = 147 days).[6] After an epidural or spinal anesthetic (tetracaine hydrochloride, 1%) was administered to the mother, we inserted catheters into two maternal hind limb arteries and a vein in all 15 sheep. These catheters were advanced into the descending aorta and inferior vena cava, respectively. In seven of the 15 sheep, a catheter was threaded retrograde into the maternal left ventricle by way of a carotid artery. Correct location of this catheter tip was established by observing the characteristic left ventricular pressure waveform. In 11 of the sheep, we opened the maternal abdomen and inserted a catheter into the uterine vein draining the horn containing the

fetus; the tip of this catheter was placed approximately 4 cm caudad to the ovary.[8] In 10 of the sheep, we incised the pregnant uterine horn and inserted catheters into two fetal hind limb arteries and a vein.[6, 7] These catheters were advanced into the fetal descending aorta and abdominal inferior vena cava, respectively. A catheter was also placed into the common umbilical vein through a periumbilical skin incision.[6] Anesthesia for catheter placements in the fetus was provided by local infiltration with lidocaine hydrochloride, 0.5%. All incisions were closed and catheters were led subcutaneously to the ewe's flank where they were stored in a pouch. The animals recovered for 2 to 7 days before any experiments were performed. We studied the unanesthetized mothers and fetuses as the ewes stood quietly in an open transport cage.

Experimental procedures. We measured uterine and umbilical blood flows, uterine and fetal oxygen deliveries, oxygen extractions, and oxygen consumptions and fetal acid-base balance at various, randomly determined levels of maternal hematocrit ranging from 30% to 8%. From the 15 animals studied, we obtained data on the uterine blood flow and uterine oxidative responses to maternal anemia (uterine responses) in seven of the sheep and on umbilical blood flow and fetal oxidative responses (fetal responses) in 10 of the sheep. To produce maternal anemia of varying degrees, we performed isovolemic exchange transfusions by infusing plasma or packed red blood cells, obtained from donor pregnant sheep, through one maternal catheter while withdrawing whole blood at the same rate from a second catheter. Hematocrits were changed slowly during 1 to 4 hours, during which time maternal and fetal aortic blood pressures (obtained with Statham P23Db pressure transducers) and heart rates (via cardiotachometers) were continuously monitored and recorded (Beckman 611A polygraph).[6] As the exchange transfusions were progressing, we periodically obtained blood samples for the determination of maternal hematocrit. When hematocrit had reached a previously selected level, we discontinued the exchange transfusion and waited for maternal hematocrit and maternal and fetal heart rates and blood pressures to be stable for at least 30 minutes.

In the studies on the uterine responses to maternal anemia, we withdrew 0.6 ml blood samples simultaneously from the maternal descending aorta and uterine vein at each hematocrit studied. Then approximately 5 to 10 × 10^6 radionuclide-labeled microspheres (15 μm diameter) were injected into the maternal left ventricle, while a reference blood sample was withdrawn from the descending aorta at 7.9 ml/min.[9] We used this high withdrawal rate during the microsphere injections to ensure that blood flow measurements made in the anemic animals were accurate.[10] In the studies on the fetal responses to maternal anemia, we obtained 0.6 ml blood samples simultaneously from the fetal descending aorta and umbilical vein, after which 1 to 2 × 10^6 microspheres were injected into the fetal inferior vena cava, while a reference blood sample was withdrawn from the fetal descending aorta at 3.9 ml/min.[6, 7] The volume of fetal blood withdrawn was replaced with an equivalent amount of fresh maternal whole blood of similar hematocrit so that fetal blood volume could be kept constant. Maternal and fetal aortic blood pressures and heart rates were stable before, during, and after microsphere injections.[9] All blood samples were analyzed for blood gases and pH, hematocrit, and blood oxygen concentration.[6, 7] Blood samples were kept on ice and were analyzed within 15 minutes. Blood gases and pH were measured at 37° C with standard electrodes and a blood gas meter (Instruments Laboratories) and were then corrected to 39° C for maternal blood samples and 39.5° C for fetal blood samples; hematocrit was measured in duplicate with the microcapillary technique; and blood oxygen concentration was measured with an oxygen analyzer (Lex-O_2-Con, Lexington Instruments). When the blood sampling and blood flow measurements were completed at any given maternal hematocrit, we changed hematocrit to a new level and repeated the measurements. For the uterine responses to maternal anemia, we made 27 observations in seven sheep; for the fetal responses, we made 33 observations in 10 sheep.

Preparation of tissues and calculation and analysis of data. At the end of the study, the sheep and fetus were killed with an overdose of pentobarbital sodium, and all catheter locations were verified visually. The uterus, placental cotyledons, placental membranes, and fetus were removed and weighed. Uterine, placental, and membrane tissues were incinerated at 280° C for 48 hours, after which the ashed tissues were packed into counting vials. The amounts of each radionuclide in the tissues and in the aortic blood reference samples were measured with a well-type gamma scintillation counter (Model 1185R, Tracor) and a 1024-channel pulse-height analyzer (Ultima II, Norland Corp).[9] Nuclide isotope separation was performed by computer (Nova 3, Data General). Aortic blood reference samples and all tissue samples contained more than 1500 microspheres to ensure that the error in any blood flow measurement was <5% at the 95% confidence limits.[9]

We computed uterine ($\dot{Q}_{ut}$) and umbilical ($\dot{Q}_{umb}$) blood flows as follows:

$$\dot{Q}_{ut} = \left(\frac{CPM_{ut}}{CPM_{ref\text{-}M}}\right)\dot{Q}_{ref\text{-}M}$$

$$\dot{Q}_{umb} = \left(\frac{CPM_{umb}}{CPM_{ref\text{-}F}}\right)\dot{Q}_{ref\text{-}F}$$

where CPM_{ut} = radioactive counts per minute in uter-

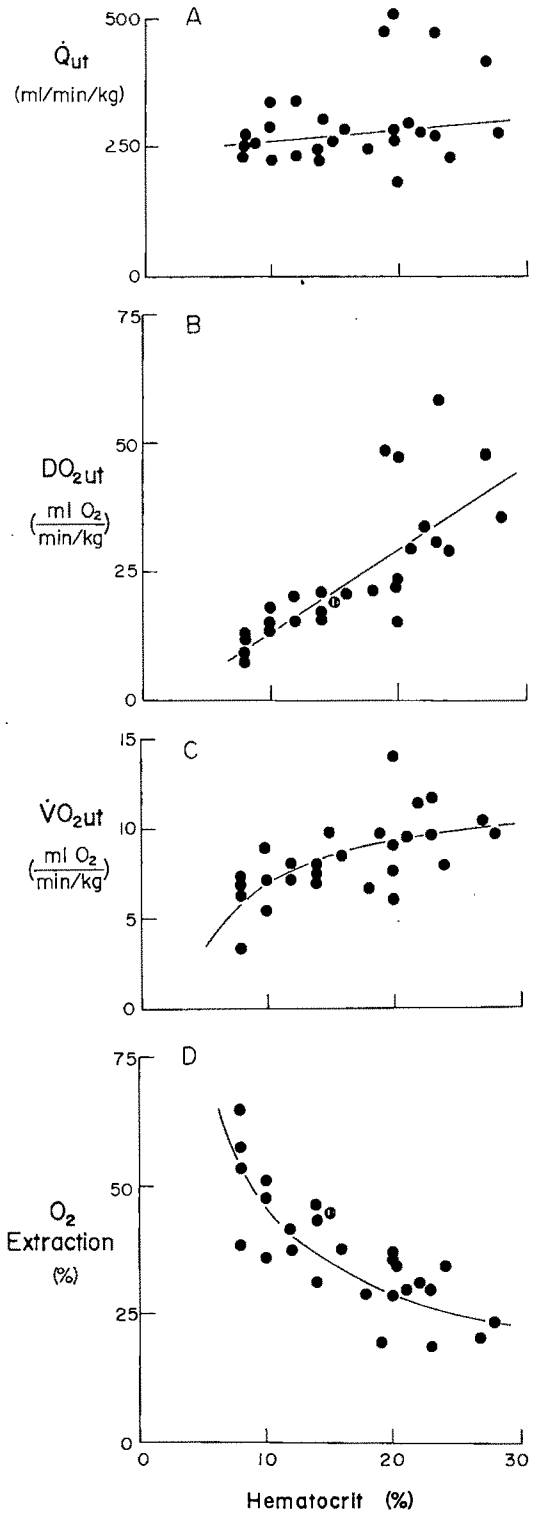

Fig. 1. Uterine blood flow ($\dot{Q}_{ut}$), uterine oxygen delivery (DO_{2ut}), uterine oxygen consumption ($\dot{V}O_{2ut}$), and uterine oxygen extraction as functions of maternal hematocrit. $\dot{Q}_{ut}$, DO_{2ut}, and $\dot{V}O_{2ut}$ are expressed per kilogram of uterus plus placenta plus fetus. *A*, $\dot{Q}_{ut}$ versus hematocrit. y = 235 + 2.7x; r = 0.21, ns. *B*, DO_{2ut} versus hematocrit. y = −4.5 + 1.73x; r = 0.78, $p < 0.001$. *C*, $\dot{V}O_{2ut}$ versus hematocrit. y = −2.2 + 3.9 lnx; r = 0.68, $p < 0.001$. *D*, Oxygen extraction versus hematocrit. $y = 194x^{-0.62}$; r = 0.79, $p < 0.001$. Analyses are based on 27 observations made in seven sheep.

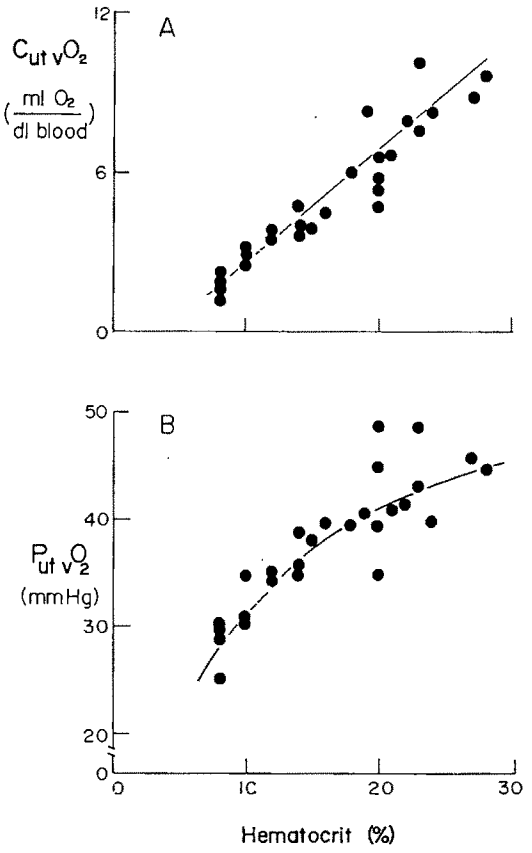

Fig. 2. Uterine venous blood oxygen concentration ($C_{utv}O_2$) and uterine venous blood oxygen tension ($P_{utv}O_2$) as functions of maternal hematocrit. *A*, $C_{utv}O_2$ versus hematocrit. y = −1.4 + 0.4x; r = 0.95, $p < 0.001$. *B*, $P_{utv}O_2$ versus hematocrit. y = 0.3 + 13.6 lnx; r = 0.91, $p < 0.001$. Analyses are based on 27 observations made in seven sheep.

ine muscle plus maternal portion of the placenta and $CPM_{ref\text{-}M}$ = radioactive counts per minute in the maternal aortic blood reference sample, both derived from a maternal injection of microspheres; CPM_{umb} = radioactive counts per minute in the fetal portion of the placenta plus the amniotic and allantoic membranes and $CPM_{ref\text{-}F}$ = radioactive counts per minute in the fetal aortic blood reference sample, both derived from an injection of microspheres into the fetal inferior vena cava; $Q_{ref\text{-}M}$ = maternal descending aortic reference blood flow; and $Q_{ref\text{-}F}$ = fetal descending aortic reference blood flow, determined by calibration of the withdrawal pumps.

Three variables of uterine oxygenation were computed with modifications of the Fick principle[8]:

$$\text{Uterine oxygen delivery } (DO_{2ut}) = \dot{Q}_{ut}\,(CaO_2)$$

$$\text{Uterine oxygen consumption } (\dot{V}O_{2ut}) = \dot{Q}_{ut}\,(CaO_2 - CutvO_2)$$

$$\text{Uterine oxygen extraction} = \dot{V}O_{2ut}/DO_{2ut} = (CaO_2 - CutvO_2)/CaO_2$$

where CaO_2 = oxygen concentration in maternal arterial blood, $CutvO_2$ = oxygen concentration in uterine venous blood, and $\dot{Q}_{ut}$ = uterine blood flow. $\dot{Q}_{ut}$, DO_{2ut}, and $\dot{V}O_{2ut}$ were expressed per kilogram of uterus + placenta + fetus.

We calculated three variables of fetal oxygenation, using the following formulas[6-8]:

$$\text{Fetal oxygen delivery } (DO_{2\ fetus}) = \dot{Q}_{umb}\ (CuvO_2)$$

$$\text{Fetal oxygen consumption } (\dot{V}O_{2\ fetus}) = \dot{Q}_{umb}\ (CuvO_2 - CuaO_2)$$

$$\text{Fetal oxygen extraction} = \dot{V}O_{2\ fetus}/DO_{2\ fetus} = (CuvO_2 - CuaO_2)/CuvO_2$$

where $CuvO_2$ = oxygen concentration in umbilical venous blood, $CuaO_2$ = oxygen concentration in fetal descending aortic (umbilical arterial) blood, and $\dot{Q}_{umb}$ = umbilical blood flow. $\dot{Q}_{umb}$, $DO_{2\ fetus}$, and $\dot{V}O_{2\ fetus}$ were expressed per kilogram of fetus.

Uterine and umbilical blood flows, arterial and venous blood oxygen concentrations and oxygen tensions, and uterine and fetal oxygen deliveries, oxygen consumptions, and oxygen extractions (dependent variables) were plotted against maternal hematocrit (independent variable). We analyzed the data statistically with a weighted least-squares method based on analysis of covariance, with which we could generate regression lines that took into account responses seen in individual animals.[11] With this method of analysis, we could define mathematically the relationships that existed between the various dependent variables and the independent variable. Linear, logarithmic, and power functions were all tested for best fit; the function selected as best describing each relationship had the greatest correlation coefficient associated with the least residual sum of squares.[11] For all analyses, p values <0.01 were used to indicate statistically significant correlations.

Results

In the 15 animals studied, gestational age was 122 ± 5 (mean ± SD) days on the day of study, maternal weight was 43 ± 6 kg, and fetal weight was 2.6 ± 0.4 kg. Maternal hematocrit before the start of the studies was 27% ± 2%. The data are presented in six figures, which illustrate the effects of maternal anemia on uterine blood flow and uterine oxygenation, the transfer of oxygen from uterine blood to umbilical blood, and the delivery of oxygen to and the consumption of oxygen by the fetus.

Uterine blood flow (Fig. 1, *A*) was independent of maternal hematocrit over the range of hematocrits studied, and therefore uterine oxygen delivery decreased linearly as a function of decreasing maternal hematocrit (Fig. 1, *B*). Despite large reductions in uterine oxygen delivery, oxygen consumption by the uterus and its contents, the placenta and fetus, decreased only slightly as hematocrit was reduced to about 15% (Fig. 1, *C*), because oxygen extraction by these tissues increased (Fig. 1, *D*). The increase in uterine oxygen extraction was reflected in decreases in uterine venous blood oxygen concentration and oxygen tension (P_{O_2}) (Fig. 2, *A* and *B*). Furthermore, the decrease in uterine venous blood P_{O_2} was associated with equivalent decreases in umbilical venous blood P_{O_2} (Fig. 3). Umbilical venous blood P_{O_2} was about 14 mm Hg less than uterine venous blood P_{O_2} over the range of maternal hematocrits studied (30% to 8%).

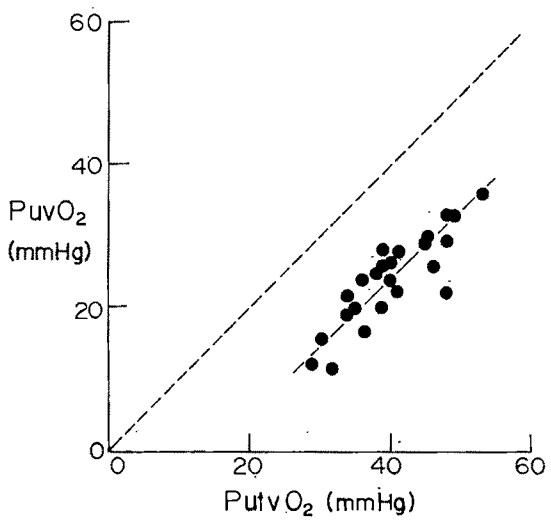

Fig. 3. Relationship of umbilical venous blood oxygen tension ($P_{uv}O_2$) to uterine venous blood oxygen tension ($P_{ut}O_2$) during acute maternal anemia. $y = -14.2 + 0.98x$; $r = 0.85$, $p < 0.001$. Analysis is based on 24 observations made in six sheep. The *dashed line* represents the line of identity.

The reductions in umbilical venous blood P_{O_2} resulting from maternal anemia led to reductions in umbilical venous blood oxygen concentration (Fig. 4, *A*). Umbilical blood flow, however, was unaffected by any level of maternal anemia produced (Fig. 4, *B*). Thus fetal oxygen delivery fell as a direct function of maternal hematocrit (Fig. 4, *C*). In response to this fall in fetal oxygen delivery, oxygen extraction (Fig. 5, *A*) increased sufficiently for fetal oxygen consumption to be maintained despite reductions in maternal hematocrit from 30% to about 15% (Fig. 5, *B*). When hematocrit was reduced to levels below about 15%, fetal oxygen consumption fell, because the further increases in oxygen extraction were insufficient to fully compensate for the further declines in fetal oxygen delivery. Since fetal oxygen extraction = $(CuvO_2 - CuaO_2)CuvO_2$, it follows that $CuaO_2 = CuvO_2$ (1 − fetal oxygen extraction). Thus increases in fetal oxygen extraction were

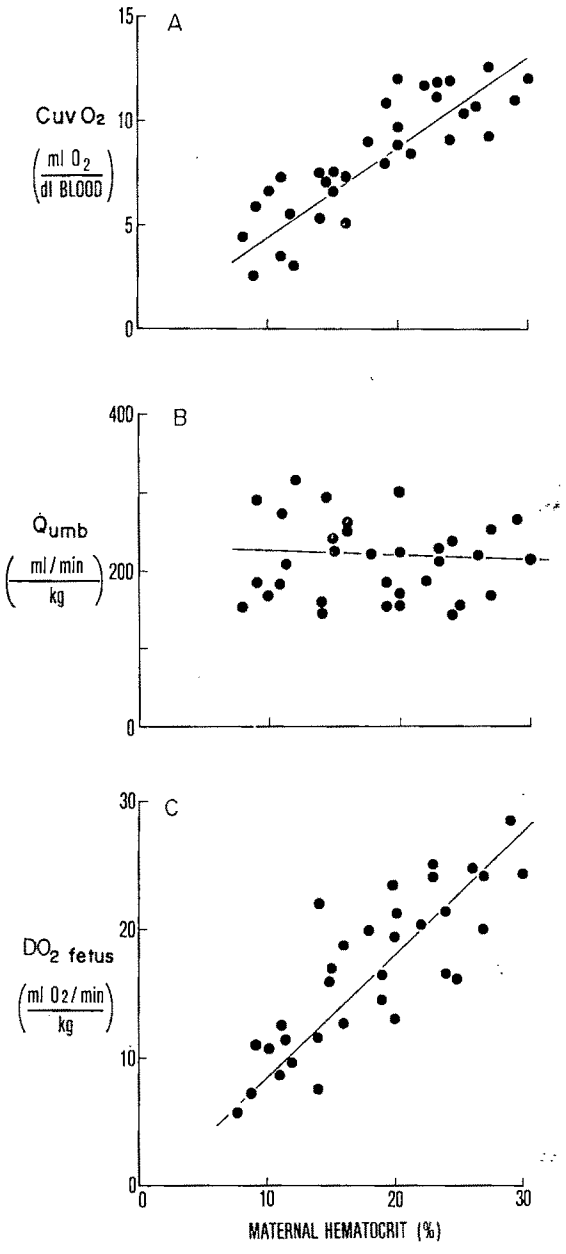

Fig. 4. Umbilical venous blood oxygen concentration ($C_{uv}O_2$), umbilical blood flow ($\dot{Q}_{umb}$), and fetal oxygen delivery ($DO_{2\,fetus}$) as functions of maternal hematocrit. $\dot{Q}_{umb}$ and $DO_{2\,fetus}$ are expressed per kilogram of fetus. *A*, $CuvO_2$ versus hematocrit. $y = 0.24 + 0.44x$; $r = 0.84$, $p < 0.001$. *B*, $\dot{Q}_{umb}$ versus hematocrit. $y = 224 - 0.66x$; $r = 0.08$, NS. *C*, $DO_{2\,fetus}$ versus hematocrit. $y = -0.15 + 0.94x$; $r = 0.81$, $p < 0.001$. Analyses are based on 33 observations made in 10 sheep.

associated with reductions in fetal arterial blood oxygen concentration: Arterial blood oxygen concentration was linearly related to maternal hematocrit ($y = -1.38 + 0.36x$; $r = 0.90$, $p < 0.001$).

Because maternal anemia led to reductions in fetal oxygen delivery and arterial blood oxygen concentration, we were also interested in identifying how thes reductions affected fetal acid-base balance. Fig. 6 show that, as long as oxygen delivery to the fetus was greate than approximately 14 ml O_2/min/kg of fetus, whic corresponded to maternal hematocrits greater tha about 15%, fetal oxygen consumption and arteri blood base excess remained within normal limits. Hov ever, when fetal oxygen delivery was ≤14 ml/min/k of fetus (maternal hematocrit ≤15%), oxygen cor sumption and arterial blood base excess both fell, ir dicating that, at these severities of maternal anemi delivery of oxygen to the fetus was inadequate for th demands for oxygen by the fetus.

Comment

The data in this report establish that acute matern anemia causes reductions in the delivery of oxygen t the uterus, placenta, and fetus. Despite such reductior in oxygen delivery, fetal oxidative metabolism can b sustained over a wide range of maternal hematocrit In our studies anemia had no significant effect on ute ine blood flow. Uterine perfusion could have change as a consequence of direct rheologic effects of the an mia on blood viscosity[2] or as a result of secondary effec of anemia on neural or endocrine vascular regulation It is possible that both of these factors were affecte equally but in opposite directions, with the net resu being that uterine blood flow did not change. Sinc anemia was associated with reductions in arterial bloo oxygen concentration, the delivery of oxygen to th uterus (uterine blood flow × arterial blood oxyge concentration) decreased linearly as a function of m ternal hematocrit. Regardless of this decrease, oxyge consumption by the uterus and its contents, the pl centa and fetus, was only minimally affected by redu tions in hematocrit, and thus in oxygen delivery, of a much as 50% below normal levels. Wilkening an Meschia[8] noted similar responses when uterine oxyge delivery was reduced ≤50% as a result of decreases i uterine blood flow. In our studies uterine oxygen cor sumption was maintained at or near normal levels whe maternal hematocrits were greater than about 15% because oxygen extraction increased as compensatio Oxygen extraction is a measure of two diffusion var ables, the capillary-to-cell P_{O_2} gradient and the capillar surface area (capillary density) available for oxygen e change.[13] The increase in uterine oxygen extractio that we observed during acute anemia could have r sulted from an increase in the P_{O_2} gradient betwee maternal-placental and fetal-placental capillaries c from an increase in the density of maternal or fet placental capillaries or both. Our data do not indica which of these diffusion variables was more likely to b affected by maternal anemia.

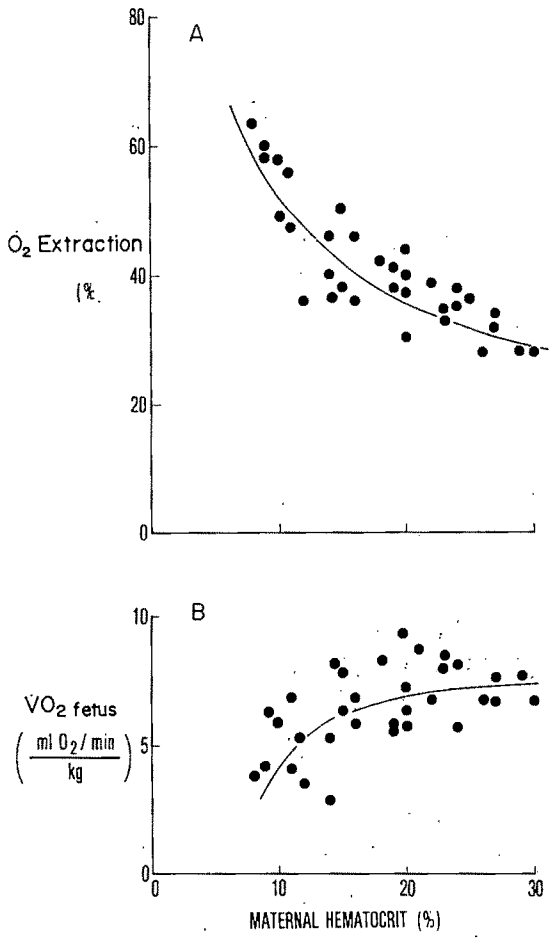

Fig. 5. Relationship of fetal oxygen extraction and fetal oxygen consumption ($\dot{V}O_{2\,fetus}$) to maternal hematocrit. $\dot{V}O_{2\,fetus}$ is expressed per kilogram of fetus. *A*, Oxygen extraction versus hematocrit. $y = .165x^{-0.50}$; $r = 0.86$, $p < 0.001$. *B*, $\dot{V}O_{2\,fetus}$ versus hematocrit. $y = (27.2\ \ln x - 50.6)/\sqrt{x}$; $r = 0.69$, $p < 0.001$. Data analyses are based on 33 observations made in 10 sheep.

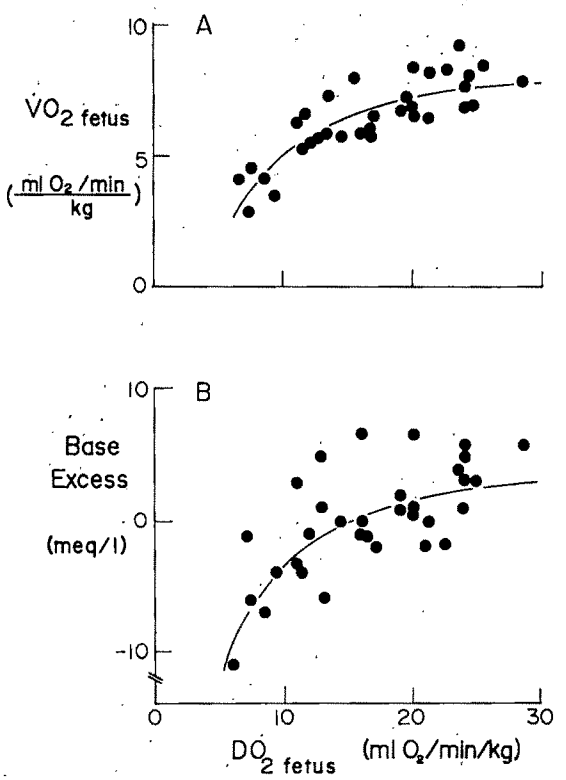

Fig. 6. Fetal oxygen consumption ($\dot{V}O_{2\,fetus}$) and fetal arterial blood base excess as functions of fetal oxygen delivery ($DO_{2\,fetus}$). $\dot{V}O_{2\,fetus}$ and $DO_{2\,fetus}$ are expressed per kilogram of fetus. *A*, $\dot{V}O_{2\,fetus}$ versus $DO_{2\,fetus}$. $y = -3.99 + 3.74\ \ln x$; $r = 0.84$, $p < 0.001$. *B*, Base excess versus $DO_{2\,fetus}$. $y = -19.9 + 7.29\ \ln x$; $r = 0.69$, $p < 0.001$. Data analyses are based on 33 observations made in 10 sheep.

The increase in uterine oxygen extraction we noted was reflected in reductions in uterine venous blood oxygen concentration and P_{O_2}. Bissonette et al.[4] observed similar responses to anemia in experiments on anemic pregnant goats. Such reductions in uterine venous blood P_{O_2} have important implications insofar as the transfer of oxygen from mother to fetus via the placenta is concerned.[14] The placentas of several species, including sheep and man, function as concurrent exchangers for oxygen. In a concurrent gas exchanger, the P_{O_2} of the blood in the donor effluent (maternal-placental venous blood, approximated by measuring P_{O_2} in uterine venous blood) must always equal or exceed the P_{O_2} of the blood in the recipient effluent (fetal-placental venous blood, approximated by measuring P_{O_2} in umbilical venous blood).[14] Our data showed that uterine venous blood P_{O_2} exceeded umbilical venous blood P_{O_2} by about 14 mm Hg over the range of maternal hematocrits studied, 30% to 8%. This relationship is similar to that observed by Wilkening and Meschia[8] and by Rankin et al.,[15] who used widely differing methods to reduce uterine venous blood P_{O_2}. Many factors could have contributed to this uterine venous-umbilical venous blood P_{O_2} difference, including uneven perfusion within the maternal-placental and fetal-placental circulations, differing hemoglobin types and hemoglobin-oxygen affinities in the maternal and fetal bloodstreams, shunting of uterine and umbilical blood flows away from placental gas exchange surfaces, and the high rate of oxygen consumption by the placenta itself.[8, 14] Although any or all of these factors could have been affected by acute maternal anemia, our data indicate that, overall, anemia had no effect on the function of the placenta as an oxygen exchanger.

Because umbilical venous and uterine venous blood P_{O_2} values were closely linked during acute maternal anemia, umbilical venous blood oxygen concentration was directly related to maternal hematocrit. Since um-

bilical blood flow was unaffected by any level of anemia produced, our studies indicate that oxygen delivery to the fetus (umbilical venous blood oxygen concentration × umbilical blood flow) was a linear function of maternal hematocrit. However, despite reductions in maternal hematocrit and thus in fetal oxygen delivery, of up to about 50%, fetal oxygen consumption was kept constant as a result of compensatory increases in fetal oxygen extraction.[6-8] As a consequence of this greater oxygen extraction, fetal arterial blood oxygen concentration was reduced. Cefalo et al.[5] also observed hypoxemia in fetal lambs whose mothers were made anemic acutely. Since oxygen supply to fetal tissues is a function of the arterial blood oxygen concentration and the tissue blood flow, fetal hypoxemia induced by maternal anemia will be associated with decreases in oxygen delivery to some fetal organs and tissues. When these decreases are severe enough, tissue anaerobic metabolism will result.[13]

The stable fetal oxygen consumption we observed during reductions in fetal oxygen delivery of up to 50% was not due to an improvement in the efficiency of placental gas exchange during maternal anemia (see Fig. 3).[8] Rather it was an indication that, under normal conditions, the delivery of oxygen to the fetus is considerably in excess of the demands for oxygen by the fetus (see Fig. 6). Reductions in fetal oxygen delivery from about 28 to about 14 ml O_2/min/kg of fetus were not associated with significant decreases in either fetal oxygen consumption or arterial blood base excess. However, when oxygen delivery was decreased to less than about 14 ml O_2/min/kg, both oxygen consumption and base excess fell as oxygen delivery became inadequate for oxygen demands. These responses are qualitatively and quantitatively the same as the responses that have been observed when fetal oxygen delivery has been reduced by other maneuvers, such as reductions in uterine blood flow[8] or umbilical blood flow[7] or the development of fetal anemia.[6] Taken together all of these experiments strongly support the concept that the level of fetal oxygen delivery, rather than the specific condition that may adversely affect oxygen delivery acutely, is more important in predicting the rate of fetal oxidative metabolism.[6, 7]

Our current data cannot and should not be extrapolated to encompass chronic degrees of anemia in animal or human pregnancies. It is unknown how chronic anemia might affect fetal oxygenation. We do, however, have preliminary data from chronically anemic pregnant sheep that indicate that fetal oxygen delivery can be reduced sufficiently to affect not only fetal oxidative metabolism but also fetal growth.

In summary, the data in the present report indica
that acute maternal anemia causes reductions in fet
oxygen delivery, for which the fetus can compensate
ensure that oxygen delivery to fetal tissues is adequa
for oxidative metabolism. When maternal anemia
sufficiently severe, however, the delivery of oxygen
the fetus becomes inadequate for the demands for ox
gen by fetal tissues. If similar responses were to
observed in human pregnancies, these responses migl
help to explain why anemic pregnant women are mo
likely to be delivered of infants who are stillborn
hypoxic at birth.

We wish to thank Anthony Battelli, Pat Moran, an
Lynn Heckman for their excellent technical assistanc

Triiodothyronine receptors in porcine granulosa cells

Najib G. Wakim, M.D., Natarajan Ramani, Ph.D., and Ch. V. Rao, Ph.D.
Louisville, Kentucky

Triiodothyronine has been found to enhance gonadotropin- and insulin-stimulated morphologic luteinization and progesterone production by porcine granulosa cells in culture. The role of triiodothyronine in the above events is not well defined. One possibility is that triiodothyronine effects are direct and are receptor mediated. To test this concept, we undertook this study to investigate the presence of triiodothyronine receptors in granulosa cells aspirated from large (6 to 12 mm), medium (3 to 5 mm), and small (1 to 2 mm) porcine ovarian follicles. Crude nuclei were isolated and tested for iodine 125–triiodothyronine specific binding. Binding was time and temperature dependent and maximal in cells from small follicles at pH 8. Scatchard analysis yielded a mean apparent dissociation constant of 5.5×10^{-9} mol/L and a mean apparent total number of binding sites of 1.0 pmol/mg of deoxyribonucleic acid. Competition experiments revealed the following relative binding affinities: triiodothyronine > L-thyroxine > reverse triiodothyronine. Gonadotropins, prostaglandins, epidermal growth factor, and insulin did not compete with ^{125}I-triiodothyronine for binding. We conclude that there are nuclear binding sites in porcine granulosa cells with characteristics expected of a triiodothyronine receptor which might mediate a direct action of triiodothyronine on granulosa cells. (Am J Obstet Gynecol 1987;156:237-40.)

Key words: Triiodothyronine receptor, granulosa cells

Nongonadotropic hormones, specifically insulin, cortisol, and thyroid hormones, have been found to affect luteinization and growth of granulosa cells in vitro in humans,[1-2] as well as in animals.[3-4] Channing et al.[4] found that insulin, cortisol, and thyroxine acted synergistically with luteinizing hormone and follicle-stimulating hormone in cultured porcine granulosa cells to enhance morphologic luteinization and progestin secretion.[4] They also found that insulin, thyroxine, and cortisol increased luteinizing hormone/human chorionic gonadotropin receptors in porcine granulosa cell cultures exposed to follicle-stimulating hormone. Thus it appears that thyroid hormones play a direct effect on granulosa cells in vitro. This role may be receptor mediated. The presence of triiodothyronine receptors in granulosa cells has never been described as far as we know. It is the purpose of this paper to demonstrate the existence of triiodothyronine binding sites in porcine granulosa cells.

Material and methods

Reagents. Unlabeled triiodothyronine and reverse triiodothyronine were purchased from Calbiochem (San Diego, California), thyroxine was obtained from Sigma Chemical Company (St. Louis, Missouri), and ^{125}I-triiodothyronine with a specific activity of 135 to 165 μCi/μg was purchased from New England Nuclear (Boston, Massachusetts). All other reagents were of the highest grade that is commercially available.

Harvesting of follicles. Porcine ovaries were obtained from freshly slaughtered pigs in a local meat packing plant. The ovaries were placed in 0.9% sodium chloride solution and transported to the laboratory on ice. Granulosa cells were harvested from small (1 to 3 mm), medium (3 to 5 mm), and large (6 to 12 mm) follicles immediately on arrival in the laboratory with the use of a 27-gauge needle and a tuberculin syringe. In the case of medium and large follicles the follicles were reflushed repeatedly with their follicular fluid during the same puncture.

Isolation of nuclei. Nuclei were extracted with salt according to a slight modification of a method described previously.[1] The follicular fluid was kept on ice while being harvested from the follicles and was centrifuged immediately after collection at 500 gm for 5 minutes at 4° C. The pellet was suspended in homogenizing buffer, pH 7.6, containing 10 mmol of Tris-hydrochloride, 3 mmol of calcium chloride, 1 mmol of dithiothreitol, and 0.25 mol of sucrose and then homogenized with use of a Teflon glass homogenizer with 12 strokes. The homogenate was centrifuged at 800 gm for 10 minutes at 4° C. Part of the crude nuclear preparation was used for deoxyribonucleic acid content estimation by means of the diphenylamine reaction with use of calf thymus deoxyribonucleic acid as the stan-

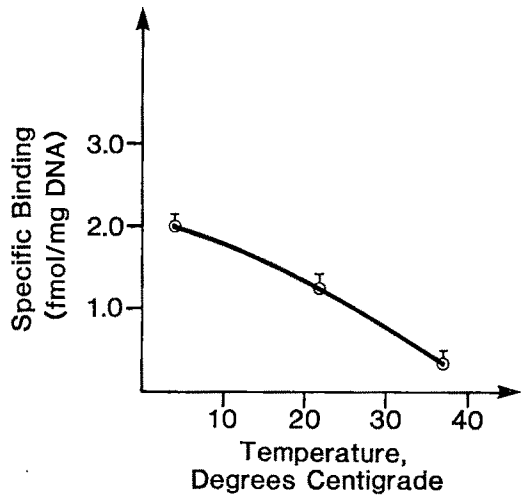

Fig. 1. Temperature dependence of ^{125}I-triiodothyronine binding by granulosa cell nuclei after 3 hours of incubation at 4° C, 22° C, and 37° C. Each assay was performed in triplicate. The *vertical bars* indicate the SEM.

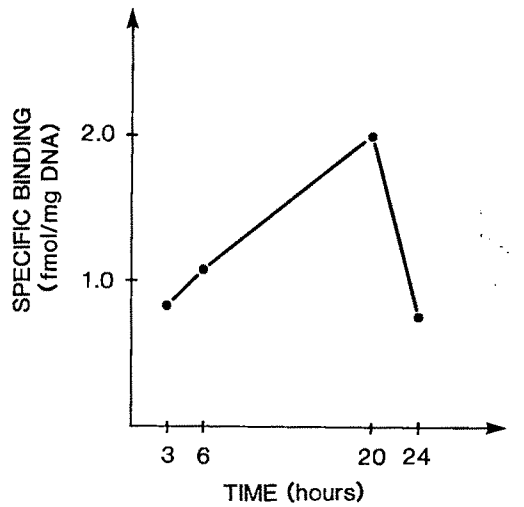

Fig. 2. ^{125}I-triiodothyronine binding as a function of time. Nuclei were isolated from granulosa cells obtained from small (1 to 2 mm) follicles as described. Aliquots of nuclear suspensions containing 14 to 15 μg of deoxyribonucleic acid were incubated in triplicate at 4° C for the indicated time periods.

dard.[5] The rest of the homogenate pellet was resuspended in the assay buffer.

Triiodothyronine binding assays. All experiments were performed on the same day of the collection of the porcine ovaries. Neither ovaries nor follicular fluid were frozen overnight. The triiodothyronine binding studies were performed by addition of 0.2 ml of the nuclear suspension (containing 14 to 15 μg of deoxyribonucleic acid in all experiments) to 12 by 75 mm tubes containing ^{125}I-triiodothyronine (at the concentrations indicated in individual experiments) in 0.2 ml of the assay buffer. A thousandfold excess of unlabeled

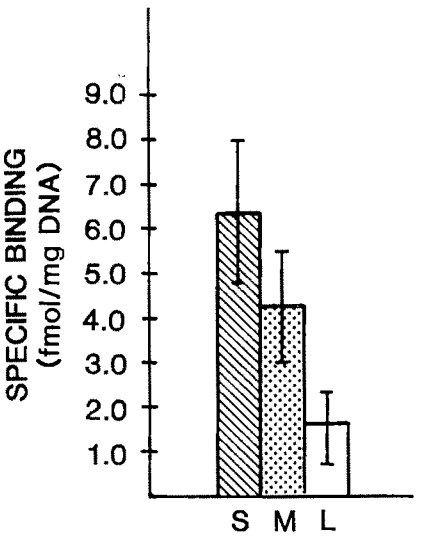

Fig. 3. ^{125}I-triiodothyronine binding to granulosa cells from porcine follicles of different sizes. *S* = Small follicles (1 to 2 mm), *M* = medium (3 to 5 mm), and *L* = large (6 to 12 mm). Mean ± 1 SD is shown. Each assay was performed in triplicate. There was a significant difference in binding between granulosa cells from small follicles and large follicles ($p < 0.01$).

triiodothyronine was used to assess nonspecific binding in parallel samples. After completion of incubations, 1 ml of assay buffer was added to each tube. The tubes were then centrifuged at 3000 gm for 20 minutes at 4° C. The supernatant was discarded, and the pellets were counted in a Beckman Auto Gamma counter with a counting efficiency of 85% for ^{125}I. Each point in the assays was determined in triplicate. Statistical significance was determined by the Student *t* test.

Results

Temperature dependence studies revealed that after 3 hours of incubation, at 4° C, 22° C, and 37° C, maximal binding occurred at 4° C, as shown in Fig. 1.

To determine the optimal time for triiodothyronine binding, the samples were incubated at 4° C for 3, 6, 20, and 24 hours. It was found that incubation of the samples for 20 hours yielded maximal binding, as seen in Fig. 2.

Granulosa cell nuclei from small (1 to 2 mm), medium (3 to 5 mm), and large (6 to 12 mm) follicles were incubated for 20 hours at 4° C to determine which population of granulosa cells would show maximal binding. There was no statistical significant difference in the binding of ^{125}I-triiodothyronine to granulosa cells obtained from small and medium follicles. However, granulosa cells from small follicles bound significantly higher amount of ^{125}I-triiodothyronine compared to granulosa cells from large follicles (Fig. 3).

Tissue dependence of triiodothyronine binding was

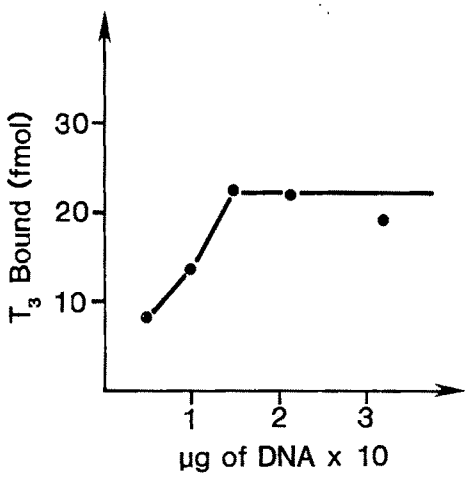

Fig. 4. Deoxyribonucleic acid dependence of triiodothyronine (T_3) binding. Nuclei were isolated from granulosa cells of small follicles (1 to 2 mm). Each assay (in triplicate) was incubated for 20 hours at 4° C.

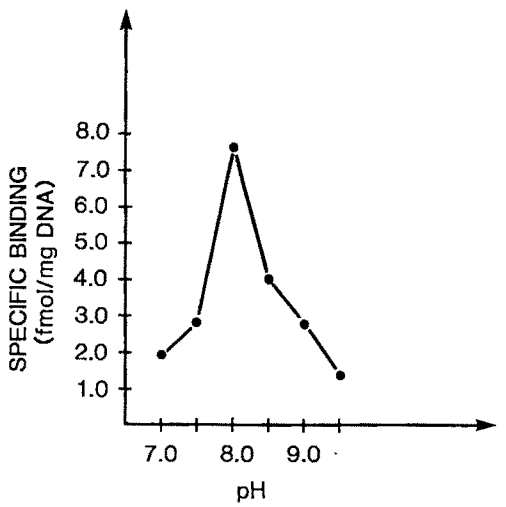

Fig. 5. ^{125}I-triiodothyronine binding as a function of pH. Nuclei were isolated from granulosa cells obtained from small (1 to 2 mm) follicles as described. Each sample (in triplicate) contained 14 to 15 µg of deoxyribonucleic acid and was incubated for 20 hours at 4° C.

Table I. Specificity of ^{125}I-triiodothyronine binding to porcine granulosa cells obtained from small follicles

Hormone	*Inhibition of binding (%)*
Triiodothyronine	50
Thyroxine	8
Reverse triiodothyronine	2
Follicle-stimulating hormone, luteinizing hormone	0
Prolactin	0
Prostaglandins E_2, $F_{2\alpha}$	0
Insulin	0
Epidermal growth factor	0

The concentrations of the different hormones are equivalent to the concentrations of triiodothyronine that caused 50% inhibition of binding (5.0 nmol/L).

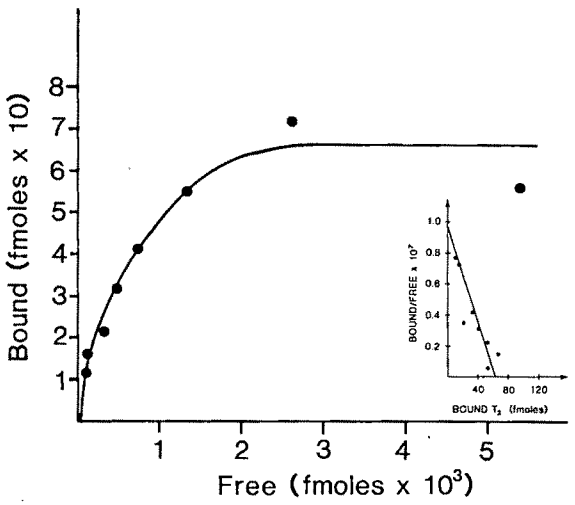

Fig. 6. Representative saturation curve of ^{125}I-triiodothyronine specific binding to nuclei of granulosa cells obtained from small follicles. Each sample (in triplicate) contained 14 to 15 µg of deoxyribonucleic acid, incubated at 4° C for 20 hours at pH 8. *Abscissa* represents free hormone and ordinate bound hormone. The *insert* illustrates a Scatchard plot of the same data.

determined over a range of deoxyribonucleic acid concentrations. As shown in Fig. 4, maximal binding was achieved at 14.44 µg.

The pH dependence of ^{125}I-T3 binding to nuclei of granulosa cells is shown in Fig. 5. The optimal pH for binding was 8.

As a result of the above findings, all further studies were done with nuclei obtained from granulosa cells of small follicles at a concentration of 14 to 15 µg of deoxyribonucleic acid. Incubations were done at 4° C for 20 hours at pH 8.

A representative saturation curve is shown in Fig. 6. This illustrates that the system is saturated under the conditions of the experiment. The Scatchard plot of ^{125}I-triiodothyronine specific binding of the same data shown in the insert of Fig. 6 is linear, indicating the presence of a single set of binding sites. The mean dissociation constant (K_d) for the binding sites obtained from several experiments was 5.5 ± 1.6 (±SEM) nmol with a range of 2.3 to 7.8 nmol. The mean number of triiodothyronine binding sites obtained from several experiments was 1083 ± 402.2 (±SEM) fmol/mg of deoxyribonucleic acid, with a range of 540 to 1867 fmol/mg.

Table I shows the results of specificity studies. Incubation with epidermal growth factor, human prolac-

tin, follicle-stimulating hormone, luteinizing hormone, insulin, and prostaglandins E_2 and $F_{2\alpha}$ in concentrations up to a 200- to 300-fold excess of unlabeled triiodothyronine showed no decrease in binding, whereas incubation with unlabeled thyroxine and reverse triiodothyronine at concentrations equivalent to the unlabeled triiodothyronine concentrations required to inhibit the specific binding of labeled triiodothyronine by 50% (about 5.0 nmol) showed only 8% and 2% inhibition of binding, respectively.

Comment

These studies demonstrate for the first time the presence of triiodothyronine binding sites in porcine granulosa cells. The affinity of these sites ($K_d = 5.5 \pm 1.6 \times 10^{-9}$ mol/L) and the number (1083 ± 402.2 fmol/mg of deoxyribonucleic acid) are comparable to those observed for triiodothyronine receptors in other mammalian tissues.[6-12] Our finding that triiodothyronine binding to porcine granulosa cells was maximal at pH 8 is consistent with the findings of others characterizing triiodothyronine receptors in other tissues.[10-11] The affinity of the binding sites in porcine granulosa cells to thyroxine (one-sixth of triiodothyronine affinity) is similar to the affinity of triiodothyronine receptors to thyroxine in other tissues.[13-15] This may reflect the relative contributions of triiodothyronine and thyroxine to hormonal activity.

We have shown that ^{125}I-triiodothyronine binding to granulosa cells from small and medium follicles was similar, while the triiodothyronine binding to granulosa cells from large follicles was significantly lower ($p < 0.01$) compared to those from small follicles. This suggests that triiodothyronine exerts maximal biologic effects early in the follicular development. By the time the follicle is in the preovulatory phase the number of triiodothyronine receptors in the granulosa cells is diminished, possibly by a down-regulating mechanism that is yet to be elucidated.

Thyroid disorders have been associated with a variety of reproductive abnormalities ranging from menstrual disorders such as amenorrhea to infertility and frequent abortions. In long-standing postpubertal hypothyroidism the ovaries may be atrophied. If hypothyroidism occurred before puberty, degenerative changes in the gonads may be found on histologic examination.[13] Alterations in the metabolism of sex hormones and a decrease in the secretion of luteinizing hormone have been offered as explanations for these aberrations in reproductive physiology.[14-15] However, the physiologic significance of these alterations remains uncertain.[13] One interesting hypothesis resulting from our work is that in cases of thyroid disease, female reproductive physiology may be influenced by a direct effect of thyroid hormones on the granulosa cells. An increase or a decrease in the amount of thyroid hormones may affect granulosa cell luteinization and thus changing progestin production by the putative corpus luteum. This may lead to reproductive failure and menstrual disturbances.

In conclusion, we have demonstrated that porcine granulosa cells contain triiodothyronine binding sites. We have shown that granulosa cells obtained from small follicles have more of these binding sites relative to those cells obtained from large follicles. Although the biologic significance of these putative receptors is not elucidated in our experiments, the previous data suggest a role for these sites in the pathophysiologic changes that are seen in cases of thyroid disease.

Epidermal growth factor deficiency during pregnancy causes abortion in mice

Osamu Tsutsumi, M.D., and Takami Oka, Ph.D.
Bethesda, Maryland

The concentration of epidermal growth factor in the submandibular gland and plasma of female mice increased substantially during pregnancy. Pregestational sialoadenectomy (removal of the submandibular glands) attenuated the rise in plasma epidermal growth factor during gestation and reduced the number of mice completing a term pregnancy by approximately 50%. Epidermal growth factor replacement therapy given to these mice during pregnancy improved the outcome of complete pregnancy to 86%. The administration of anti–epidermal growth factor antiserum in a daily dose of 50 or 100 μl to sialoadenectomized pregnant mice increased the percentages of abortion to 67 and 100, respectively. These results suggest that epidermal growth factor may be necessary for the normal course of pregnancy. (AM J OBSTET GYNECOL 1987;156:241-4.)

Key words: Epidermal growth factor, pregnancy, abortion, submandibular gland

The polypeptide epidermal growth factor (molecular weight = 6045) is produced in large amounts in mouse submandibular glands and is also present in the circulation.[1] Hormones such as testosterone and progestins increase the production of epidermal growth factor in the submandibular gland.[2,3] Epidermal growth factor has been shown to stimulate cell proliferation in various types of mammalian cells in culture, but its physiologic function has not been well defined.[1] The concentration of epidermal growth factor in the submandibular gland and plasma has been found to increase during gestation.[4] In this study we examined the possible physiologic role of epidermal growth factor in pregnancy by assessing the effect of epidermal growth factor deficiency on the outcome of pregnancy. Epidermal growth factor deficiency was produced by either removal of the submandibular gland before gestation or administering anti–epidermal growth factor antiserum to pregnant mice. Epidermal growth factor deficiency during pregnancy was found to increase the incidence of abortion, which suggests that epidermal growth factor is necessary for the normal course of pregnancy.

Material and methods

C3H/HeN virgin female mice were obtained from the Small Animal Section of the National Institutes of Health. At 5 to 6 weeks of age, sialoadenectomy (surgical removal of submandibular glands) was performed with the mice under ether anesthesia. Three weeks after the operation, when they were fully recovered, they were mated with mature C3H/HeN male mice of established fertility. Age- and weight-matched female mice with sham operation were also mated at the same time. The presence of a vaginal plug was checked daily in the morning, and the day of its detection was designated as day 1 of pregnancy. Pregnant mice were caged individually and maintained under controlled temperature (25° C) with 12 hours of light (8:00 AM to 8:00 PM) and 12 hours of darkness. Pregnancy was defined as complete when the pregnant mice gave birth to live pups. The number and weight of newborn pups were determined at the time of birth. Mice that did not complete the pregnancy were put to death on day 21 and the uteri were examined with a dissecting microscope. The number of implantation sites, if present, was checked at various times during pregnancy. The crown-rump length of the fetus was measured by a microscope fitted with a graduated eyepiece.

Epidermal growth factor concentrations in the submandibular gland and plasma of virgin and pregnant mice were determined by radioimmunoassay with the use of the liquid phase double-antibody method as reported before.[4] Blood was obtained from the trunk vein with the animal under ether anesthesia and centrifuged. The plasma was aspirated and stored at −20° C until use. Submandibular gland tissues were excised, weighed, and homogenized in phosphate-buffered saline. The homogenate was centrifuged at 12,000 g for 20 minutes at 4° C and the supernatant was removed and stored at −20° C until use.

Antimouse epidermal growth factor antibody pre-

Table I. Epidermal growth factor concentrations in the submandibular gland and plasma of mice during pregnancy

Mice	n	Epidermal growth factor concentrations		
		Submandibular gland (ng/mg wet tissue)	Plasma (ng/ml)	Mice with detectable levels (>0.1 ng/ml) (%)
Normal virgin	8	43 ± 13	0.16 ± 0.07	38
Pregnant, day 1	7	52 ± 20	0.19 ± 0.12	57
Pregnant, day 3	7	64 ± 13	0.31 ± 0.32	57
Pregnant, day 5	7	73 ± 12	0.25 ± 0.22	57
Pregnant, day 7	7	105 ± 30	0.23 ± 0.13	71
Pregnant, day 9	7	113 ± 30	0.26 ± 0.12	86
Pregnant, day 11	6	164 ± 36	0.52 ± 0.58	100
Pregnant, day 15	6	195 ± 35	0.76 ± 0.63	100
Pregnant, day 19	6	197 ± 29	0.67 ± 0.77	100
Sialoadenectomized virgin	7	None	<0.1	0
Pregnant, day 7	7	None	<0.1	0
Pregnant, day 11	4	None	<0.1	0

Results are given as mean ± SD.

pared in rabbit (Collaborative Research, Waltham, Massachusetts) was administered subcutaneously to sialoadenectomized mice and normal controls in a volume of 50 to 100 μl daily between days 5 and 10 of pregnancy. The anti–epidermal growth factor antiserum was capable of binding 200 μg of epidermal growth factor per 100 μl as determined by a modified Ouchterlony[5] double immunodiffusion method. Normal rabbit serum was injected in the same way. Epidermal growth factor (Collaborative Research, culture grade), 5 μg dissolved in 100 μl of physiologic saline, was administered subcutaneously to sialoadenectomized mice daily from day 7 to 19 of pregnancy. The dose and timing of anti–epidermal growth factor antibody and epidermal growth factor injections yielding optimal effects were determined by preliminary experiments. The mice weighed 20 to 25 gm at the time of treatment.

Results

The concentration of epidermal growth factor in the submandibular gland and plasma increased progressively during pregnancy (Table I). In virgin mice 38% had detectable levels of plasma epidermal growth factor but the incidence increased to 100% on day 11 of pregnancy and thereafter. The plasma epidermal growth factor levels of the sialoadenectomized virgin and pregnant mice were below the level of sensitivity of the assay (<0.1 ng/ml). These results suggested that the submandibular gland may be the major source of plasma epidermal growth factor.

All of the normal mice completed 20 days of pregnancy and gave birth to an average of 7.2 ± 1.6 (SD) pups per mother (Table II). The average weight of the pups was 1.35 ± 0.13 (SD) gm at birth. In contrast, 52% of the sialoadenectomized, pregnant mice completed term pregnancy; the average number of pups decreased to 4.2 ± 1.5 (SD) per mother, and the average birth weight was 1.24 ± 0.09 (SD) gm. These values were significantly lower than those of pups born to normal mice ($p < 0.01$). However, the pups born to sialoadenectomized mothers grew normally. Examination of the uteri of sialoadenectomized mice who did not complete term pregnancy revealed that the resorption sites were found in only 20%, whereas eight of 10 sialoadenectomized pregnant mice apparently had no resorption sites.

Administration of anti–epidermal growth factor antiserum to sialoadenectomized pregnancy mice further decreased the number of mice completing term pregnancy (Table II). Daily injection of 50 or 100 μl anti–epidermal growth factor antiserum reduced the pregnancy success levels to 33% and 0%, respectively. Administration of normal serum had no adverse effects on the outcome of pregnancy. Furthermore, treatment of normal pregnant mice with 100 μl of anti–epidermal growth factor antiserum did not appreciably affect the outcome of the pregnancies.

Table III shows the fetal size on day 11 of pregnancy. The fetal crown-rump length was 4.12 ± 0.30 (SD) mm in normal pregnant mice and 3.34 ± 0.58 (SD) mm in sialoadenectomized pregnant mice. Anti–epidermal growth factor treatment given to sialoadenectomized pregnant mice further reduced the fetal crown-rump length to 3.10 ± 0.42 (SD) mm.

The uteri of sialoadenectomized mice were found to develop normally up to day 7 of gestation and contained approximately the same number of implanted sites as those of normal mice, 8.2 ± 1.0 and 8.4 ± 1.5, respectively. Thus it appeared that epidermal growth factor deficiency produced by sialoadenectomy affected

Table II. The effect of pregestational sialoadenectomy, epidermal growth factor replacement, and administration of anti–epidermal growth factor antiserum on the outcome of completed pregnancies in mice

Mice	*n*	*Treatment*	*Incidence of complete pregnancy (%)*	*Significance*
Normal	18	None	100	
Sialoadenectomized	21	None	52	$p < 0.001$
Sialoadenectomized	9	Anti–epidermal growth factor, 50 μl*	33	$p < 0.001$

Table III. The number and size of fetuses in normal, sialoadenectomized, and anti–epidermal growth factor treated, sialoadenectomized 11-day-pregnant mice

Mice	*No. of fetuses per mother*	*Crown-rump length (mm)*	*Total No. of fetuses*
Normal	7.8 ± 1.5	4.12 ± 0.30	31
Sialoadenectomized	7.3 ± 1.0	3.34 ± 0.58*	29
Sialoadenectomized and anti–epidermal growth factor treated†	7.3 ± 1.3	3.10 ± 0.42*	29

*Significant differences were found between normal and sialoadenectomized mice ($p < 0.05$) or anti–epidermal growth factor treated sialoadenectomized mice ($p < 0.01$).
†Anti–epidermal growth factor treatment was given to sialoadenectomized pregnant mice daily at a dose of 100 μl from day 5 to day 10 of gestation. Data represent mean ± SD. Four pregnant mice were used in each group.

neither the fertilization and implantation of oocytes nor the embryonic development until day 7 of gestation but at some later stage it induced abortion. Therefore, it is conceivable that epidermal growth factor replacement therapy begun on day 7 might reduce the rate of abortion. The data in Table II indicated that 86% of epidermal growth factor–treated, sialoadenectomized mice completed term pregnancies. Epidermal growth factor replacement therapy, however, did not significantly increase the number and weight of pups at birth.

Comment

The concentration in the submandibular glands and plasma of female mice increased during pregnancy, and sialoadenectomy was found to reduce the circulating level of epidermal growth factor to undetectable levels. These results confirm the previous findings and support the view that the submandibular gland is a major source of plasma epidermal growth factor in mice.[4] It is likely that the increase in submandibular gland epidermal growth factor during pregnancy is caused by a rise in the circulating levels of progestins and/or androgens[6] inasmuch as these steroid hormones have been shown to increase the concentration of epidermal growth factor in the gland.[2, 3]

Our study also shows that a significant number of sialoadenectomized pregnant mice were unable to complete a term pregnancy. However, this defect was largely corrected by epidermal growth factor replacement therapy during pregnancy. In addition, administration of anti–epidermal growth factor antiserum to sialoadenectomized pregnant mice decreased the likelihood of completing a term pregnancy. These results suggest that epidermal growth factor is important to the normal course of pregnancy in mice.

Anti–epidermal growth factor antiserum given to sialoadenectomized mice further exacerbated the unfavorable outcome of pregnancies. The plasma levels of epidermal growth factor in these mice were too low to be detectable. These findings raise the possibility that there may be other source(s) of epidermal growth factor beside the submandibular gland. Indeed, the presence of immunoreactive epidermal growth factor–like substance in the uterus has been reported.[7] It is conceivable that the uterus produces such a substance that plays a role in the process of pregnancy.

At present, the mode of involvement of epidermal growth factor in pregnancy is not known. The finding that epidermal growth factor replacement therapy was largely effective when it was started on day 7 of pregnancy, at which time implantation has already taken place,[8] suggests that epidermal growth factor plays a role in the postimplantation period. Our data indicate that deficiency of epidermal growth factor results in reduced development of the fetus and an increased rate of abortion. Possible target organs for epidermal growth factor include the fetus and the uterus, both of which have been shown to possess epidermal growth factor receptors.[9-12] It is also possible that epidermal growth factor helps to maintain pregnancy by facilitating the production of female sex steroid hormones in the ovary.

Previously, epidermal growth factor has been implicated in the growth of the mammary gland, another organ that undergoes extensive development during pregnancy.[13, 14] These studies, together with the present findings, suggest that epidermal growth factor is an important physiologic agent for cellular growth and development during pregnancy.

Intrauterine growth retardation after long-term maternal salicylate administration in the rabbit

Jeffrey C. Lukas, M.D., Ted S. Rosenkrantz, M.D., John R. Raye, M.D., Patricia J. Porte, and Anthony F. Philipps, M.D.

Farmington, Connecticut

The effects of chronic maternal salicylism on fetal growth were studied in chronically catheterized pregnant rabbits. Graded intravenous infusions of sodium salicylate were given continuously between days 22 and 29 of gestation. Maternal plasma salicylate concentrations (mean ± SD) of 12.0 ± 1.6 mg/dl (low-dose group) or 24.1 ± 5.3 mg/dl (high-dose group) were achieved. Control rabbits were infused with saline solution. Pups were delivered by hysterotomy on day 29. Fetal/maternal salicylate concentration ratios were near unity for both infusion groups. There were significant dose-related reductions (mean ± SD) in fetal weight (control, 39.7 ± 6.7 gm; low-dose group, 34.4 ± 6.4 gm; high-dose group, 22.2 ± 7.1 gm; $p < 0.001$) and in crown-rump length (control, 9.7 ± 0.45 cm; low-dose group, 9.1 ± 0.68 cm; high-dose group, 7.7 ± 0.86 cm; $p < 0.001$). There was a significant reduction in fetal brain weight only in the high-dose group, and brain weight/fetal weight ratios were increased, suggesting relative sparing of brain growth. Liver weight was significantly reduced in both low- and high-dose groups. In contrast to results in previous animal studies, standardized intravenous maternal salicylate administration in rabbits induced a reproducible and dose-dependent asymmetrical fetal growth retardation. (Am J Obstet Gynecol 1987; 156:245-9.)

Key words: Salicylates, maternal, fetal, growth, intrauterine growth retardation

The widespread use of aspirin during pregnancy[1] has prompted several investigations of the effects of salicylate ingestion during pregnancy on fetal development. Reduced fetal growth has been reported as one such consequence in several animal studies[2, 3] but was an inconsistent finding in others.[4] Clinical studies in humans regarding the effects of salicylates on fetal growth are conflicting as well. An Australian study reported a significant reduction in birth weight associated with high-dose maternal salicylate ingestion[5, 6] while a large retrospective study in the United States[7] with less use of medication by mothers could find no such relationship. In both animal and clinical studies various parameters describing drug exposure, including route and length of salicylate administration, dosage, and amount absorbed, were inconsistent in some cases and poorly defined in others. Given this variability in both methods and results, the purpose of the present study was to investigate the role of salicylates as a possible retardant of fetal growth in late gestation. A chronically catheterized pregnant rabbit preparation was used with defined sodium salicylate intravenous infusions in the last trimester of gestation to examine the fetal effects of salicylate exposure during this period of rapid fetal growth.

Material and methods

Eleven New Zealand White does were studied according to the guidelines for care and use of laboratory animals of the Department of Health and Human Services. At operation, with the animals under light ketamine anesthesia, polyvinyl catheters were implanted into the external jugular vein. The catheters were tunneled subcutaneously to the nape of the neck, leaving approximately 1 cm of catheter exposed. After a recovery period of 7 days, the does were mated and divided into three groups: a low-dose group with target maternal plasma salicylate levels of 10 to 15 mg/100 ml (four does), a high-dose group with target salicylate concentrations of >20 mg/100 ml (three does), and a saline-infused control group (four does). On day 19 of gestation, the rabbits were placed into an infusion harness consisting of a vinyl neck collar attached to a vest attached around the thorax of the animal. An extension of the catheter coursed from the infusion harness through a protective metal spring tether loosely attached to the top of the cage, allowing for free access to food and water. After 3 days' acclimation to the har-

ness, the does were weighed and preinfusion blood samples were drawn from an ear vein as blanks for plasma salicylate determinations.

Continuous intravenous infusions were conducted from day 22 to day 29, with the use of an external syringe pump (Orion Instruments, Cambridge, Massachusetts). The four control does were infused with normal saline solution at a rate of 1.2 ml/hr. The four low-dose rabbits were infused with 60 mg of sodium salicylate (Torigian Laboratories, Queens Village, New York) per milliliter of sterile water solution at the same rate to attain a target maternal plasma salicylate level of 10 to 15 mg/dl. For the infusions of the three does in the high-dose group, higher concentrations of the infusate (80 to 120 mg/dl) were infused at the same rate to attain a target level of >20 mg/dl. Daily maternal blood samples were drawn to monitor maternal plasma salicylate levels, which also allowed for adjustment of the high-dose infusate concentration to maintain maternal plasma sodium salicylate levels near the target value for that group.

On day 29, each doe was weighed and final maternal blood samples were drawn before the animals were put to death. The fetuses were delivered by hysterotomy and the following measurements were recorded for each fetus: body weight, crown-rump length, brain weight, liver weight, and placental weight. Fetal blood samples were obtained via cardiac puncture for determination of plasma salicylate concentration.

The salicylate assay performed on plasma samples was done by spectrophotometric analysis of the chelation of iron by salicylic acid. All data are presented as the mean ± SD. Statistical significance of the results was determined with the one-way analysis of variance, Student's unpaired t test, and χ^2 analyses. Linear regression analysis was performed by means of the least-squares method.

Results

Table I presents the pertinent maternal and fetal study characteristics. There was a total of 96 fetuses from 11 gestations. The average litter size was not statistically different between groups. Fetal mortality was noted only for the high-dose group; however, when survivability was compared by χ^2 analysis, the groups were not significantly different. Maternal weight decreased slightly during pregnancy in all three groups; the magnitude of this loss was not significantly different between groups.

As demonstrated in Table II, maternal plasma salicylate levels averaged during the infusion period were significantly different for the two experimental groups: 12.0 ± 1.59 mg/dl for the low-dose group and 24.1 ± 5.28 mg/dl for the high-dose group. When fetal plasma salicylate levels were compared with maternal levels obtained at delivery, fetal:maternal ratios close to 1 were attained.

The fetal growth parameters are presented in Table III. Mean fetal weight was significantly decreased for the salicylate-treated groups (34.4 ± 6.4 and 22.2 ± 7.1 gm for low-dose and high-dose groups, respectively), when compared with the mean fetal weight of 39.7 ± 6.7 gm for saline-treated controls. As shown in Fig. 1, when all fetal data were pooled, a negative relationship between fetal plasma salicylate concentration and fetal weight was observed ($r = -0.64$, $p < 0.001$). In addition, fetal crown-rump length was significantly decreased for both experimental groups when compared with controls. A dose-dependent response, similar to that noted for the reduction in fetal weight, was observed (Fig. 2). Calculated ratios of fetal weight per centimeter of crown-rump length (Table III, Fig. 3), however, revealed significant and dose-related decrements below the control values.

Selected fetal organ weights were compared between control and salicylate-treated groups, as shown in Table III. Placental weight was significantly decreased for both experimental groups. The placental weight:fetal weight ratio was unchanged for the low-dose group and

Table III. Fetal growth parameters compared between control and treated groups

	Control (n = 31)	*Low-dose (n = 39)*	*High-dose (n = 26)*
Fetal weight (gm)	39.7 ± 6.7	34.4 ± 6.4 ($p < 0.001$)	22.2 ± 7.1 ($p < 0.001$)
Crown-rump length (cm)	9.7 ± 0.45	9.1 ± 0.68 ($p < 0.001$)	7.7 ± 0.86 ($p < 0.001$)
Weight:length ratio (gm/cm)	4.07 ± 0.54	3.75 ± 0.48 ($p < 0.001$)	2.81 ± 0.64 ($p < 0.001$)
Placental weight (gm)	6.40 ± 1.49	5.34 ± 1.41 ($p < 0.001$)	4.49 ± 1.03 ($p < 0.001$)
Placental:fetal weight ratio	0.16 ± 0.033	0.16 ± 0.040 (NS)	0.21 ± 0.045 ($p < 0.001$)
Liver weight (gm)	3.03 ± 0.42	2.37 ± 0.73 ($p < 0.001$)	1.50 ± 0.27 ($p < 0.001$)
Liver:fetal weight ratio	0.078 ± 0.012	0.068 ± 0.013 ($p < 0.001$)	0.072 ± 0.018 ($p < 0.05$)
Brain weight (gm)	1.00 ± 0.08	1.04 ± 0.11 (NS)	0.77 ± 0.17 ($p < 0.001$)
Brain:fetal weight ratio	0.026 ± 0.003	0.031 ± 0.005 ($p < 0.001$)	0.037 ± 0.009 ($p < 0.001$)

was significantly increased for the high-dose group compared with that of controls. A striking reduction in liver weight was apparent, with 22% and 50% decrements observed in low-dose and high-dose groups, respectively. The liver weight:fetal weight ratios for both experimental groups were significantly lower than the control group value. A decrease in brain weight (24% decrement) was noted only in the high-dose group. The fetal brain:body weight ratio increased significantly from a control value of 2.6% ± 0.3% of body weight to 3.1% ± 0.5% and 3.7% ± 0.9% of body weight for low- and high-dose groups, respectively ($p < 0.001$).

Comment

Aspirin (sodium acetylsalicylic acid) is a ubiquitous medication. Several surveys have suggested that it is the most commonly used drug during pregnancy.[1] Experimental animal and clinical human studies addressing the possible effects of maternal aspirin ingestion on fetal development have recently been reviewed.[6, 8] Among the adverse effects reported are an increased incidence of congenital anomalies,[6] reduced fetal growth,[2, 3, 5] increased length of gestation,[6] deleterious effects on the fetal circulation (premature ductus arteriosus closure, pulmonary arterial hypertension),[10] and decreased neonatal hemostasis.[11] Studies of the effects of salicylate use on fetal growth in animals have produced varying results. A significant decrease in fetal body weight after maternal ingestion of 250 mg of aspirin per kilogram per day throughout gestation has been reported in rats.[2] A significant reduction in the birth weight of rabbit pups born to does ingesting 250 mg of aspirin per kilogram per day from day 8 to day 12 of a 32-day gestation has been reported.[3] However, other animal studies have found no significant reduction in litter weight, litter size, or individual fetal weights[4] attributable to aspirin.

Human studies are also inconclusive regarding the effect of salicylate ingestion during pregnancy on fetal growth. An Australian study[5, 6] focused on 64 mothers who ingested large quantities of aspirin through habituated use (two to 12 daily doses) of "headache powders" containing 600 to 700 mg per dose of aspirin or related salicylates. A significant reduction in birth weight was found, and this decrease was found to be related to the number of years the preparation had been taken before pregnancy. A dose-dependent response was also suggested. The U.S. Collaborative Perinatal Project[7] examined the birth weight of infants born to 1515 mothers described as experiencing "heavy" exposure to aspirin during pregnancy (defined as aspirin taken at least 8 days a month for at least 6 months during the pregnancy). No significant decrease in birth weight was found in this group. The authors recognized, however, that the magnitude of ingestion of aspirin was less for study mothers than for the subjects in the Australian study.

Significant problems with data interpretation are apparent when the information available from both animal and human salicylate studies is evaluated. Variability in dosage of drug ingested, inconstancy of blood salicylate concentrations, and variation in length of exposure to salicylates during pregnancy make it difficult to draw firm conclusions from these studies regarding the effects of maternal salicylate exposure on fetal growth. In contrast to previous animal studies, this series of experiments performed in chronically catheterized rabbits was designed to assess changes in fetal growth related to a state of chronic and stable maternal salicylism, as defined by serial measurements of ma-

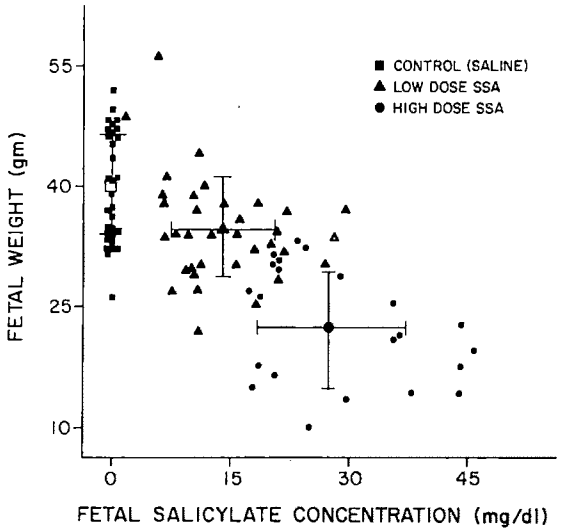

Fig. 1. Relationship between fetal plasma salicylate concentration and fetal weight (fetal weight = −0.51 sodium salicylate, in milligrams per 100 ml, + 40.10, n = 88, r = −0.64, $p < 0.001$).

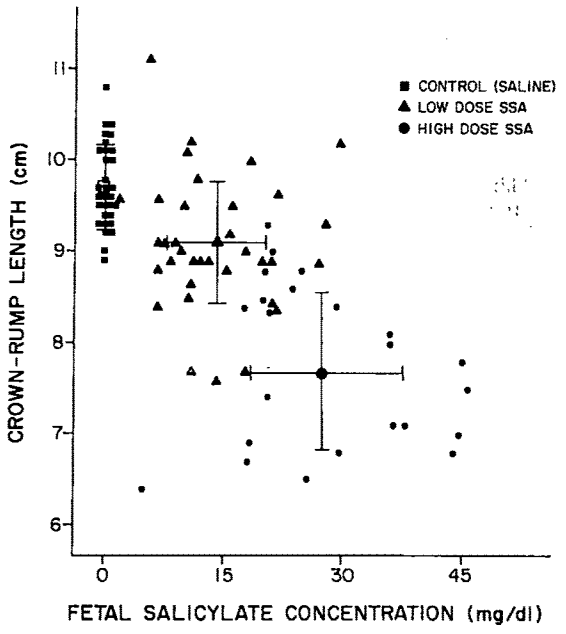

Fig. 2. Relationship between fetal plasma salicylate concentration and fetal crown-rump length (crown-rump length = −0.05 sodium salicylate, in milligrams per 100 ml, + 9.77, n = 88, r = −0.70, $p < 0.001$).

ternal salicylate concentrations in blood. Intravenous administration of salicylates bypassed the inherent variability of oral ingestion and gastrointestinal absorption. Sodium salicylate was used in these series of experiments because of its relative solubility in water when compared with the acetyl ester. Many pharmacologic actions are shared by both drugs, including depression of prostaglandin synthesis via inhibition of the enzyme

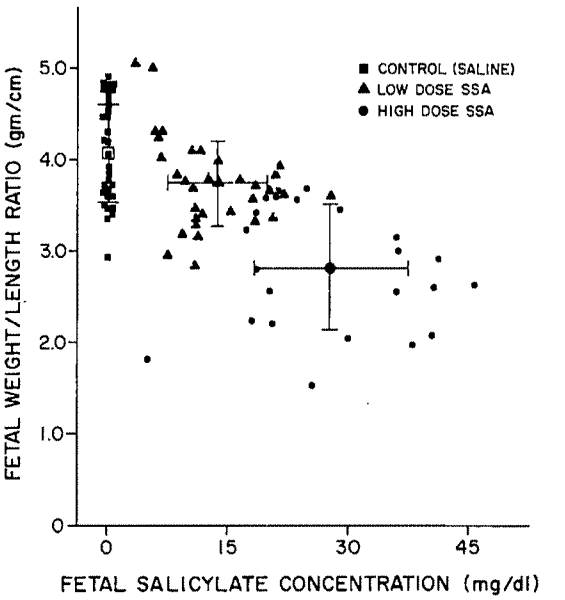

Fig. 3. Relationship between fetal plasma salicylate concentration and fetal weight-length ratio (weight/length = −0.03 sodium salicylate, in milligrams per 100 ml, + 4.06, n = 89. r = −0.60, $p < 0.001$).

cyclo-oxygenase.[1, 12] Most importantly, aspirin is rapidly converted to salicylate after ingestion with 30% to 50% hydrolyzed to salicylate before systemic distribution, both during transport through gut epithelium and during first pass through the liver.[1, 12, 17] In addition, sodium salicylate has little effect on fetal ductal closure[8, 14] and on uterine blood flow,[12, 13] significant causes of fetal mortality in experimental animals[13] in studies with the use of aspirin. The third-trimester infusion period was chosen as a time of most rapid fetal growth.

This series of graded continuous infusions of sodium salicylate in the pregnant rabbit during late gestation resulted in a level of exposure to salicylates in the fetus similar to that in the mother, in agreement with previous observations[1] of fetal: maternal salicylate concentration ratios similar to unity. The present study found a dose-dependent decrement in fetal growth. Fetal weight was affected in greater proportion than skeletal growth as demonstrated by decreased weight: length ratios. There was relative sparing of fetal brain growth with increased brain weight: fetal weight ratios. Liver growth appeared most affected, as shown by significant decreases in liver weight: fetal weight ratios. Placental weights were significantly decreased for both experimental groups, while placental weight: fetal weight ratio was increased only for the high-dose group. This pattern of reduction in fetal body weight and, to a lesser degree, length with relative sparing of brain growth is typical of the asymmetrical intrauterine growth retardation seen in late gestation.

The mechanisms responsible for the inhibition of fetal somatic growth are unclear. Maternal weight gain was poor during pregnancy in this study but no differences between salicylate-treated or saline-infused mothers were observed. It is of interest, however, that previous investigators have noted poor maternal weight gain during salicylate exposure in animals despite adequate food intake.[5] Both aspirin and sodium salicylate are known to be potent inhibitors of aerobic glycolysis and oxidative phosphorylation.[12] Experimental evidence suggests that these effects are not mediated by inhibition of prostaglandin synthesis and that aspirin may be an inhibitor of glycolysis only after conversion to salicylate. Thus a salicylate-induced defect in fuel utilization and/or energy production may have been responsible for the inhibition of both the maternal and the fetal weight gain observed. Alternatively, salicylates have been shown to impair glucose-induced insulin secretion from the fetal pancreas in a dose-related manner.[14] This salicylate-mediated inhibition of insulin release could result in decreased growth, as fetal insulinopenia has been associated with fetal growth retardation in experimental rats[15] and in human case studies.[16]

One can only speculate as to the relevance of this salicylate effect found in rabbits to the human situation. In the human adult, total salicylate concentration 1 hour after ingestion of two standard tablets, or 650 mg, is approximately 7 mg/dl.[17] After ingestion of three tablets, or 975 mg, one could expect a 1-hour postingestion level of at least 10 mg/dl. Thus three aspirins taken every 4 hours could provide peak maternal and fetal plasma salicylate concentrations in the range chosen for the low-dose rabbit infusions in this experiment. This level of ingestion is comparable with that of mothers in the Australian study.

In summary, the present study suggests that chronic sodium salicylate intake in the last trimester of gestation causes a dose-dependent reduction in fetal weight with the development of asymmetrical growth retardation. The mechanisms for the salicylate-induced growth retardation are unclear but may relate to the effects of salicylates on economy of fuel utilization by mother and fetus.

A monoclonal antibody to a cell surface determinant in human endometrial epithelium: Stage-specific expression in the menstrual cycle

John D. Aplin, Ph.D., and Mourad W. Seif, M.D.
Manchester, England

A monoclonal antibody (CC25) was obtained after immunization of mice with intact glandular epithelial cells from secretory phase endometrium. Here we report a preliminary immunohistologic study in the endometrium of 29 patients in different phases of the menstrual cycle and early pregnancy. In immunofluorescence, CC25 binds to a basolaterally oriented epithelial cell surface antigen that is absent during the proliferative phase and appears suddenly in both glandular and uterine surface locations soon after ovulation. In mid and late secretory phase, the level of expression diminishes slowly. The epitope is absent from glandular epithelial cells in first-trimester decidua. However, it is associated with vascular smooth muscle cells in endometrium and decidua. CC25 promises to be a useful reagent for the analysis of endometrial function during the menstrual cycle. (Am J Obstet Gynecol 1987;156:250-3.)

Key words: Monoclonal antibody, endometrium, cell surface, epithelium, menstrual cycle

Hormone-driven alterations in the structure of the human uterine endometrium during the menstrual cycle are well documented in the histologic literature.[1] Such changes reflect the preparation of the tissue to accept and support an implanting blastocyst 6 or 7 days after ovulation. Relatively little, however, is known about the biochemical changes underlying this remodeling process. Maternal influences over the epithelium, which may occur by hormonal mechanisms or by direct interaction with endometrial stroma, are likely to be exerted at basal epithelial cell surfaces. In contrast, the blastocyst must attach initially to components of apical cell surfaces. Thus functional requirements in the tissue suggest the likelihood of compositional variations between different cell surface domains. The cell surface acts as an important intermediary in the process of preparation for implantation, and so changes in its composition are to be expected corresponding to the different phases of the menstrual cycle.

We have made monoclonal antibodies against cell surface determinants of endometrial epithelial cells and have already demonstrated, using these probes, that the expected asymmetry of composition is present between apically and basally disposed areas of the cell surface[2] (Seif MW, Aplin JD. A monoclonal antibody recognising apical surfaces of glandular but not luminal epithelial cells in human endometrium. Unpublished observations). We now report on an antibody that recognizes an epitope, the expression of which varies dramatically during the menstrual cycle. This marker has considerable diagnostic potential in assessing the response of the target tissue to hormonal changes and ovulation, as well as its preparation to accept the implanting blastocyst.

Material and methods

Endometrial tissue was obtained at curettage in the secretory phase, as judged initially from the last menstrual period and confirmed later by histologic studies. Epithelial cells were isolated and used as immunogen in mice, and antibody-secreting hybridoma cell clones were isolated and recloned as described previously.[2] Screening was by double immunofluorescence on acetone-fixed air-dried cryostat sections of snap-frozen human endometrium from various stages of the menstrual cycle. Scoring (as shown in Fig. 4) was made by comparing intensities of fluorescence of slides stained under identical conditions in which positive and negative control specimens were included in each series. Scoring was on a scale of − to 4+. With practice, scores are reproducible between different observers. Decidua was obtained at termination of pregnancy at 8 to 10 weeks' gestation. It was snap-frozen in liquid nitrogen and sectioned and examined as for endometrium. The epitope recognized by monoclonal antibody CC25 is destroyed by procedures involved in paraffin embedding.

Fig. 1. Immunofluorescent staining of early secretory phase endometrium with monoclonal antibody CC25. Note fluorescence associated with basolateral surfaces of glandular cells. (×600.)

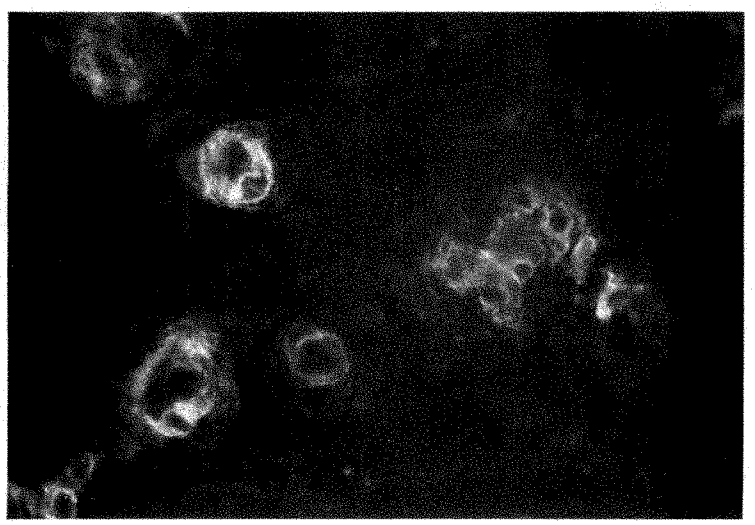

Fig. 2. Immunofluorescence of mid secretory phase endometrium demonstrating the CC25 epitope in the media tunica of small blood vessels. (×600.)

Results

Antibody CC25 recognizes an epitope associated with the basolateral surfaces of epithelial cells both in glandular (Fig. 1) and uterine luminal endometrium. Staining is absent from apical cell surfaces of epithelial cells and the underlying stroma is also negative. Smooth muscle cell layers in the walls of small and medium sized blood vessels are also positive (Figs. 2 and 3).

The CC25 epitope shows a strong menstrual cycle variation (Fig. 4), being completely absent from glandular and luminal epithelial cells in the proliferative phase and making a sudden appearance shortly after ovulation (Figs. 1 and 4).

The exact timing of this appearance in the epithelium in response to ovulation must await further study, since curettings from early secretory phase are obtained infrequently. In mid and late secretory phases, staining with CC25 shows a gradual reduction in intensity (Fig. 4) and a slightly more diffuse distribution based on scoring of different phase endometria stained under the same conditions. The epitope is still confined to basolateral areas of epithelial cells, however, being absent from apical surface. By the time of the menstrual phase, it is lost. In one case of "variable secretory activity" (as assessed by standard histologic examination) the intensity of staining also varies in different glands

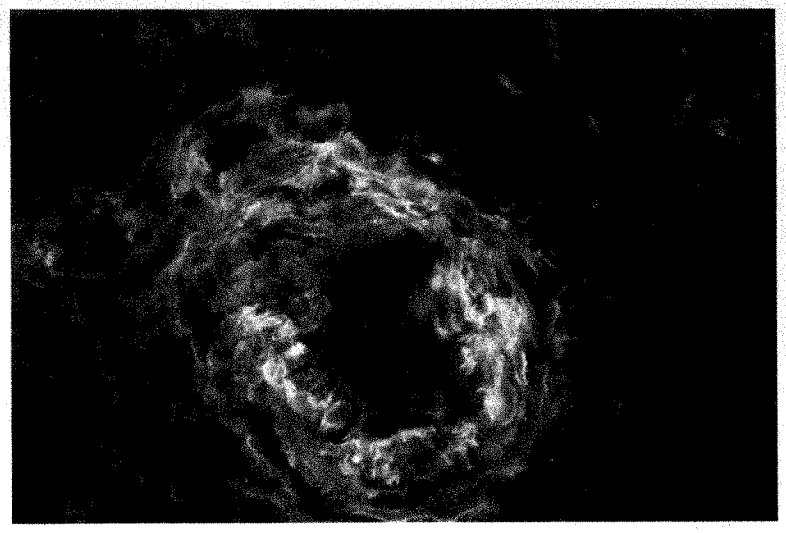

Fig. 3. Immunofluorescence demonstrating the presence of CC25 epitope in a decidual blood vessel. Some interstitial staining is also visible. (×600.)

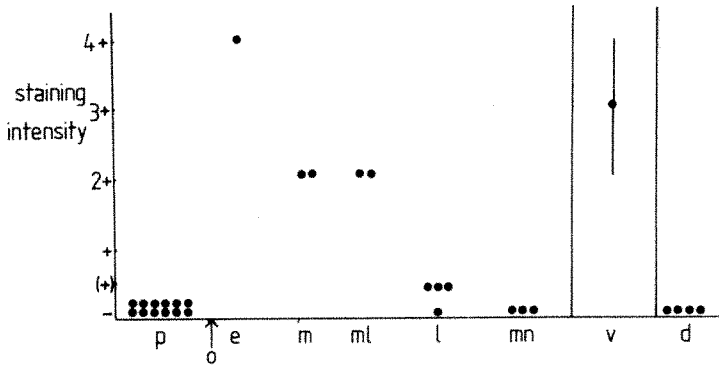

Fig. 4. Expression of CC25 in glandular endometrial epithelial cells assessed by imunofluorescence in 29 patients at different stages of the menstrual cycle and in the first trimester of pregnancy: *p*, proliferative; *o*, ovulation; *e*, early secretory; *m*, mid secretory; *ml*, mid-late secretory; *l*, late secretory; *mn*, menstrual; *v*, variable secretory activity; *d*, first-trimester decidua.

(Fig. 4). This variation (from moderately to strongly positive) is apparent between adjacent glands in the same field of view. Vascular smooth muscle cell layers, in contrast, stain throughout the menstrual cycle with equal intensity (Fig. 2). This staining persists in first-trimester decidua (Fig. 3), where some scattered staining is also associated with a subpopulation of interstitial cells.

Comment

The present study represents an attempt to analyze at a molecular level the changes that occur in the structure of endometrial tissue during the menstrual cycle to provide new parameters for the evaluation of function. The epitope recognized by CC25 undergoes a rapid increase of expression in glandular cells from an undetectable level in proliferative phase to a maximal level after ovulation. The exact timing of this change and the nature of its hormonal control requires further study with use of carefully selected groups of patients in whom hormonal measurements are also available. However, the observation that in a sample of 12 proliferative phase endometria (as assessed clinically and histologically) all were negative suggests strongly that the appearance of the CC25 epitope represents an early response to hormonal changes occasioned by ovulation. Simple dependence on progesterone is ruled out by the absence of the marker from gland cells in the first trimester of pregnancy and by its association with vascular smooth muscle throughout the cycle and in the first trimester. CC25 therefore recognizes a novel marker of endometrial function. The location of the

epitope at basolatleral cell surfaces in glandular as well as surface epithelium suggests a function associated with the response of the epithelial cells to the maternal environment, and biochemical characterization of the carrier molecule may provide insight into its function.

As a marker related to the earlier secretory phase endometrium, however, the CC25 epitope provides a tool for the assessment of endometrial function in a range of clincial situations. These include the detection of ovulation, the staging of the endometrial response, and the diagnosis of abnormal endometrial function. Such approaches may aid in evaluation of patients undergoing artificial insemination and in vitro fertilization, as well as in assessment of subsequent ability of the endometrium to support a pregnancy. They may also add a new parameter to the diagnosis of infertility arising from endometrial dysfunction in response to ovulation.

Comparison of serum progesterone levels in dogs after administration of progesterone by vaginal tablet and vaginal suppositories

L. David Fulper, M.S., Robert W. Cleary, Ph.D., Ernest C. Harland, D.V.M., Ahmed H. Hikal, Ph.D., and Alan B. Jones, Ph.D.
University, Mississippi

Serum progesterone levels from a vaginal tablet formulation and six different vaginal suppository formulations, each containing 25 mg of progesterone, were evaluated in mongrel dogs. Bioavailabilities relative to an intravenous dose of progesterone were calculated. The vaginal tablet was found to have a significantly higher bioavailability compared with the vaginal suppositories. (Am J Obstet Gynecol 1987;156:253-6.)

Key words: Progesterone, suppositories, vaginal tablets

Absorption of progesterone from the intestinal tract is prompt, but the compound is rapidly transformed as a result of the first-pass effect of the liver and possibly also during absorption through the intestinal mucosa.[1] In the 1950s, orally effective compounds with progestational activity (progestins) became available. However, the actions of these compounds differ in some respects from that of progesterone.[2] For this reason progesterone supplementation is often accomplished via vaginal suppository.[3,4]

The vehicle used in the manufacture of a suppository can influence the bioavailability of progesterone.[5,6] Water-soluble polyethylene glycol bases and fatty type bases such as cocoa butter have been used in progesterone suppository formulations. Vaginal tablets have been used to deliver drugs such as nystatin and clotrimazole; however, no progesterone vaginal tablet formulations have been reported in the literature.

To assess the performance of a vaginal tablet formulation of progesterone, the in vivo release of progesterone from a vaginal tablet and six suppository formulations have been compared.

Material and methods

Progesterone vaginal tablets containing 25 mg of progesterone were prepared by wet granulation on a Korsch single-punch tablet press (Eweka-G.m.b.H., Frankfurt, Germany) with the use of a 15 mm double concave punch and die set. The tablet weights were 1 gm nominal. Tablet hardness was 8 to 10 kp (kilopond) nominal.

Suppositories containing 25 mg of progesterone were prepared by the fusion method.[7] Micronized progesterone (Paddock Laboratories, Inc., Minneapolis, Min-

nesota) was dissolved in the melted base and poured into a mold (Armstrong, Millville, New Jersey). The resulting suppositories were 2.8 cm long and 1.1 cm in diameter. The following bases were used for the manufacture of fatty type suppositories: Witespol H-15 (Riches-Nelson, Inc., Greenwich, Connecticut), Fattibase (Paddock Laboratories, Inc., Minneapolis, Minnesota), and cocoa butter (Woltra, New York, New York). The following bases were used to manufacture water-soluble suppositories: Cetomacrogol 1000 (Pflatz and Bauer, Inc., Waterbury, Connecticut), Polybase (Paddock Laboratories, Inc.) and a polyethylene glycol suppository with a base composition of polyethylene

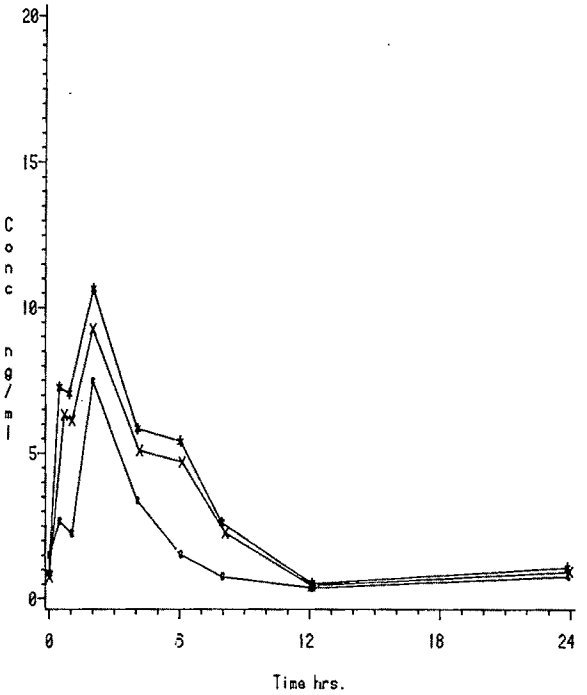

Fig. 2. Serum progesterone levels for vaginal formulations. * = Fattibase; ● = Witespol H-15; X = cocoa butter.

glycol 1500, United States Pharmacopeia, 96% (Fisher Scientific Co., Fair Lawn, New Jersey), and polyethylene glycol 4000, United States Pharmacopeia, 4% (Jefferson Chemical Co. Inc., Houston, Texas).

The water-soluble suppositories and the vaginal tablet formulations were assayed for content uniformity by use of a method reported by Roffe et al.[8] The fatty suppositories were assayed for content uniformity by a modification of the same assay method, whereby the suppository was first dissolved in hexane and an aliquot of this solution was evaporated and reconstituted with methanol before assay.

An intravenous progesterone solution was prepared by dissolving 50 mg of micronized progesterone in 25 ml of ethanol. This solution was diluted 1:1 with normal saline solution immediately before injection.

The vaginal formulations were evaluated in female mongrel dogs weighing between 13 and 23 kg. The ovaries and uterus were removed from each dog approximately 4 weeks before the study and the dogs allowed to acclimate before the study began. The dogs were divided into two groups. Group 1 received fatty-type suppositories and the vaginal tablet. Group 2 received water-soluble suppositories and the vaginal tablet. Dosing order for each group was according to standard Latin square protocol. A 7-day washout period was observed between doses. The dogs were fasted the night before dosing. They were anesthetized with sodium thiamylal and the suppository or tablet was in-

serted vaginally with a plastic tampon applicator. The dogs were allowed to recover from anesthesia and blood was drawn by venipuncture at time 0 and nominally at 0.5, 1, 2, 4, 6, 8, 12, and 24 hours for assay.

Progesterone, 0.25 mg/kg intravenously, was administered to male dogs. The dogs were anesthetized with pentobarbital sodium for the entire experiment. Blood was drawn by venipuncture at time 0 and nominally at 0.08, 0.15, 0.25, 0.50, 1, 2, 4, and 6 hours for assay.

The blood was allowed to clot, and the serum was separated by centrifugation and stored at −40° C, unless the assay was to be performed within 48 hours, in which case it was stored at 10° C. Radioimmunoassay was done with Coat-A-Count progesterone radioimmunoassay kits (Diagnostic Products Corp., Los Angeles, California) according to the manufacturer's protocol.[3] The tubes were counted with an AutoGamma Counter 500C (Packard Instruments, Downers Grove, Illinois).

Results

Because of problems associated with the assay both groups were actually assayed twice. Dog 6 expelled the suppository on week 2 of the second run and died on week 3 of the second run. Inasmuch as the order of dosing was identical in both runs, data from the first run for weeks 2 to 4 were used for this dog in order to maintain a balanced Latin square.

A terminal disposition rate constant for progesterone was calculated from data generated in a separate intravenous study in male dogs. Male dogs were used for the study instead of female dogs mainly for convenience. The data from this study supported preliminary results obtained in female dogs.

Representative plots of the serum data are presented in Figs. 1 and 2. The data for each dog were normalized with respect to dose. The area under the curve from time 0 to infinity was calculated by the trapezoidal rule and the terminal disposition rate constant (obtained from intravenous data). The percent bioavailability was calculated relative to an intravenous dose. The mean and standard deviation for the area under the curve and bioavailability for each formulation are presented in Table I.

Analysis of the combined data from both groups with the use of a one-way analysis of variance resulted in the resolution of two homogeneous subsets of formulations that were statistically different ($p < 0.05$) from each other. Subset 1 contained only suppositories. Subset 2 contained only vaginal tablets. Because there was no statistical difference observed between the vaginal tablets that were common between both groups, the data were pooled and analyzed with a single one-way analysis of variance.

The times to attain peak plasma concentration for the suppositories ranged from 0.6 to 1.3 hours and peak plasma concentration for the vaginal tablet was seen after 1.9 hours.

Comment

Although no statistical difference was demonstrated between the different suppository bases, a clear trend can be seen with respect to bioavailability of progesterone from the water-soluble and fatty type suppositories. It is interesting to note the apparent lower performance of the polyethylene glycol formulation compared with the Polybase formulation, which is also a blend of polyethylene glycols.

The decline in serum concentration of progesterone with the vaginal tablet was slower than that for the suppositories. This behavior is typical of absorption rate–limited elimination. With absorption rate–limited elimination the rate constant for absorption is smaller than the rate constant for elimination, and the time course of the drug in the body becomes a reflection of its absorption from the dosage form. Absorption rate–limited elimination would be expected for drugs with a short half-life such as progesterone.

Assuming concentration-independent kinetics, if two formulations of equal dose are administered by the same route and different areas under the curve are noted, the formulation with the lesser bioavailability is being eliminated before complete absorption can take place. In the case of vaginal administration this is most likely by vaginal expulsion of the formulation. With the exception of dog 6, as noted, no intact suppositories were found in the pens. However, vaginal discharges were occasionally noted after insertion of both suppositories and vaginal tablets. It may be possible that as the suppositories disintegrated, either by dissolution or by melting, they were discharged from the vagina. The faster the disintegration, the sooner the formulation could be expelled from the vagina. This explanation gains some basis when one considers that the polyethylene gylcol formulation, a water-soluble formulation, was designed to dissolve in the same time period that it took the fatty type bases to melt, hence its similarity in performance to cocoa butter, Witespol H-15, and Fattibase formulations.[6] The vaginal tablet, on the other hand, would be expected to absorb fluids as it disintegrates and not form a sufficient amount of fluid to induce an excessive discharge. Cetomacrogol and Polybase, being slower dissolving water-soluble bases, tend to fall between the fast-disintegrating suppositories and the vaginal tablet with its extended residence time.

When a drug is being evaluated for the treatment of a condition, the release profiles of the formulation de-

livering this drug should be considered. The evaluation of the formulations in this study indicates a significant advantage in terms of bioavailability for the vaginal tablet (approximately twice the area under the curve of the next highest formulation) over vaginal suppositories. Increasing the ability of a formulation to resist expulsion from the vagina should be considered to increase the residence time in the vagina and hence the bioavailability.

Papanicolaou smears in diagnosis of endocervical chlamydial infection

To the Editors:

We wish to support Dr. Shafer and colleagues (Am J Obstet Gynecol 1985;151:765-71) in concluding that Papanicolaou-stained cervical smears have no place in the definitive diagnosis of endocervical chlamydial infection.

In our study, of 45 women who were chlamydia positive by either culture, monoclonal antibody-stained smears (Microtak, Syva UK), or both, only six (13%) had inclusions in Papanicolaou smears suggesting chlamydial infection.[1] Furthermore, such abnormalities were also found in Papanicolaou smears from 10 (13%) of 76 chlamydia-negative patients. The highly specific and sensitive chlamydial monoclonal antibody test[2] was used to support culture, reducing the likelihood of false negative results. Chlamydial inclusions may be disrupted while obtaining endocervical material or preparing specimens for analysis, but epithelial cells with intact cytoplasmic chlamydial inclusions are seen in <5% of specimens by the monoclonal technique.[1] Therefore it is not surprising that inclusions, characteristic of chlamydial infection, are rarely seen in Papanicolaou smears.

Midforceps deliveries

To the Editors:

I am constrained to reply to the article of Dierker et al. (Midforceps delivery: Long-term outcome of infant. Am J Obstet Gynecol 1986;154:764-8). Nowhere, either in this well-written paper or in the discussion that followed (although there were a number of caveats), did I see any mention of the importance of evaluation of pelvic architecture in assessing the potential outcome of the labor and delivery. Over the years there has been ample documentation of the role of subtle variations in the bony pelvis (android and anthropoid) productive not only of disproportion but of secondary soft tissue insufficiency as well. Clinical evaluation of this structure, it seems to me, should play an important part in a resident's training to better prepare him to make a seasoned judgment in those instances in which reasonable progress in labor is not being made.

Alex S. Tulsky, M.D.

Reply

To the Editors:

I appreciate Dr. Tulsky's comments regarding our article on midforceps delivery. Maternal pelvic architecture plays a significant role in second-stage dystocia along with other factors such as epidural anesthesia. As mentioned in the article, the role of epidural anesthesia was not prospectively evaluated, so the relationship between epidural anesthesia and the need for midforceps delivery could not be adequately evaluated in our study.

In a similar fashion, pelvic architecture—ranging from clinical adequacy of the pelvis to pelvic type (android, platypellic, etc.)—was infrequently described in the delivery note. Consequently the association between pelvic architecture, difficulty of delivery, and neurological sequelae in the infant could not be addressed. A discussion of pelvic architecture and forceps delivery has been well covered by authors such as Pierce and Danforth in Danforth's text on obstetrics and gynecology.

Preeclampsia

To the Editors:

Sibai et al. (Maternal and perinatal outcome of conservative management of severe preeclampsia in midtrimester. Am J Obstet Gynecol 1985;152:32-7.) quote our paper[1] as demonstrating the adverse fetal outcome of conservatively managed preeclampsia. Nowhere in our paper is it stated that the 24 patients were "treated conservatively with bed rest and anti-hypertensive therapy." In fact, as stated in the paper, six

Table I. Outcome of all pregnancies complicated by sustained proteinuria and hypertension managed by the high-risk team at the John Radcliffe Maternity Hospital in 1984

	Duration of proteinuria (days)

Range	168-254	199-257	197-260	180-238	224-281
Survival (n)	10	10	10	3	6
Percent	83	100	100	75	100
Reasons for delivery†					
Spontaneous labor	1	0	0	0	1
Maternal	3	3	3	0	1
Fetal	3	1	3	1	0
Maternal plus fetal	1	1	0	0	0
Prophylactic	3	5	4	2	4
Intrauterine death	1	0	0	1	0

*All known to have proteinuria before pregnancy.

†A "maternal" or "fetal" reason for delivery was one where it was considered that the continuation of the pregnancy carried an immediate risk to the safety of mother or child. A "prophylactic" reason was one where it was considered better to deliver than to continue with the pregnancy, but there was no immediate risk to mother or child.

women were delivered within 24 hours of admission and four of these were within 6 hours of admission. Fetal loss occurred in only four cases. Two cases of intrauterine death occurred before the women's admission to the hospital. One case of neonatal death occurred in a woman delivered within hours of admission on fetal and maternal grounds, and one neonatal death occurred at 32 days of age in the case of a woman who had been admitted and treated with Labetalol for 3 days before delivery that was precipitated by a deteriorating nonstress test.

It is our policy to undertake conservative management of proteinuric preeclampsia occurring before 36 weeks only if the following criteria are met: (1) The mother is asymptomatic. (2) Her blood pressure can be controlled at safe levels. (3) There are no biochemical or hematologic abnormalities indicating the pregnancy cannot safely be continued. (4) There is no evidence of fetal distress sufficient to require delivery on nonstress tests, which are usually performed daily.

Failure to apply these criteria will inevitably result in major maternal morbidity as experienced by Sibai et al. The outcome of pregnancies with sustained proteinuria and hypertension managed by the high-risk team at the John Radcliffe Hospital in 1984 is given in Table I. No significant maternal morbidity was experienced.

We would agree with Sibai et al. that much of the maternal morbidity experienced in their study occurred because of delayed delivery, although clearly some of the complications related to inadequate blood pressure control. We believe, however, that in many pregnancies complicated by preeclampsia it is possible to safely undertake conservative management with close maternal and fetal monitoring and immediate delivery when any of the above criteria for conservative management are no longer met.

Reply

To the Editors:

We would like to apologize to both Drs. Moore and Redman regarding the above misquote, which actually applies to another reference. This must have happened during the process of revision and reduction of the number of references in the manuscript. The main reason their study was included in the references is to refer to the four perinatal deaths they reported for gestations ≤29 weeks. This holds true also for other references in our paper.

The rest of the material and data included in their letter is irrelevant to the substance of our report. Their suggestion that some of the complications were related to inadequate blood pressure control is not based on

any solid clinical or scientific data. In fact, there is no evidence to suggest that reducing maternal diastolic blood pressure to <90 mm Hg in these patients will reduce the incidence of any of the complications listed in our report. However, lowering the diastolic blood pressure to <90 mm Hg as suggested by them will increase the incidence of fetal growth retardation, as demonstrated in their report (82% were ≤10 percentile). The patients included in their table are far from being comparable to the patients studied in our report. The definition of preeclampsia used by them applies to mild-to-moderate preeclampsia and not severe (blood pressure ≥140/90 mm Hg or systolic increased by 30 mm Hg and/or diastolic increased by ≥15 mm Hg; 24-hour urine protein ≥1 gm). The patients had severe preeclampsia at time of delivery (as reflected in their maximum antenatal blood pressure values). In addition, the authors excluded all cases of ≤24 weeks' gestation, while 31 patients studied in our report had disease at <25 weeks' gestation.

Moreover, 34 of the 60 patients reported by us received their management elsewhere and then were referred to us because of maternal or fetal complications.

The average gestational age at delivery in our patients was 26.5 ± 1.9 weeks whereas it ranged between 31 ± 3.5 to 33 ± 3.0 weeks in the groups listed in their table. In fact, during a 1-month period in 1984 we encountered a similar number of patients with gestational ages comparable to those listed in that table. Hence the information in that table is irrelevant, since it applies mainly to mild preeclampsia developing during the third trimester.

Fetal lung maturity

To the Editors:

I read with great interest the article entitled "Amniotic fluid phosphatidylglycerol and phosphatidylcholine phosphorus as predictors of fetal lung maturity" (Kogon et al. Am J Obstet Gynecol 1986;154:226-30).

The authors state that the analysis of their data was made with the use of standard diagnostic test parameters. However, sensitivity is usually defined as the likelihood that a test will be positive if the disease is present. Conversely, specificity is the likelihood that the test will be normal or negative if the disease is absent.[1]

In this application, the occurrence of respiratory distress syndrome (RDS) is the disease. The positive test result which indicates the possibility of RDS is the absence of phosphatidylglycerol.

Table I. RDS in relation to phosphatidylglycerol determination (<2 days before delivery)

Phosphatidylglycerol	*No RDS*	*RDS*
Present	592 (a)	10 (b)
Absent	28 (c)	36 (d)

Sensitivity $\frac{d}{b+d} = 78.3\%$

Specificity $\frac{a}{a+c} = 95.5\%$

False positive rate $\frac{c}{a+c} = 4.5\%$

False negative rate $\frac{b}{b+d} = 21.7\%$

Positive predictive value $\frac{d}{c+d} = 56.3\%$

Negative predictive value $\frac{a}{a+b} = 98.3\%$

Prevalence $\frac{b+d}{a+b+c+d} = 6.9\%$

In this light, the results of the authors' Table I might be better presented as shown in the Table I of this letter.

Reply

To the Editors:

Drs. Walker and Simon make a good point, one which was given great consideration by myself and my coauthors during the writing of the paper.

Sensitivity and specificity are used in the assessment of a test to predict an outcome. This outcome generally is the presence of a disease but not always, as our paper attests.

The presence of the particular phospholipids in amniotic fluid as predictive of an outcome was assessed. That outcome in this case is health (fetal pulmonary maturity) as opposed to disease. In fact, the measure of the outcome was lack of disease (neonatal respiratory distress syndrome). So, although this does not conform exactly to the more usual use of sensitivity and specificity, the format is more appropriate for this study,

inasmuch as the test is to determine a healthful state as opposed to a diseased state.

Drs. Simon and Walker make the point that "the positive test result which indicates the possibility of RDS" is the absence of phosphatidylglycerol. This is not only very different from what we found and wish to state, which is that the positive test result that indicates the improbability of RDS is the presence of phosphatidylglycerol, but it is also very untrue. The results showed that the absence of phosphatidylglycerol is not a good predictor of RDS. That is why the quantification of phosphatidylcholine phosphorus and its correlation to RDS was assessed. In the absence of phosphatidylglycerol, fetal pulmonary maturity could be determined by the measurement of phosphatidylcholine phosphorus.

For this reason it was felt data were best presented as they appeared, but I do thank Drs. Simon and Walker for their time and concern.

Preterm labor

To the Editors:

In their article (Preterm labor: Its diagnosis and management. AM J OBSTET GYNECOL 1986;154:3-8) Drs. Gonik and Creasy state "no increased iatrogenic risks from preterm serial examinations of the cervix have thus far been identified." Perhaps this depends on the technique of examination (paracervical versus intracervical), because Lenihan[1] showed a significant relationship between antepartum pelvic examinations and premature rupture of the membranes. This may largely explain the failure of Main et al.[2] to reduce premature birth by their interventions; an astounding 50% of the women in their Preterm Labor Prevention Clinic population in Philadelphia had premature rupture of the membranes. Similar pathophysiologic conditions may underlie the threefold increase in premature rupture of membranes caused by recent coitus,[3] and also explain the reported ability of erythromycin to extend gestation in women treated for idiopathic preterm labor.[4] A study looking at the method of cervical examination and recent intercourse in relationship to premature rupture of membranes might be very fruitful.

Reply

To the Editors:

We welcome Dr. Arlen's interest in our article and appreciate the opportunity to respond to his comments. The basis for our statement "no increased iatrogenic risks from preterm serial examinations of the cervix" comes from the personal experiences of one of us with this approach to the high-risk preterm labor candidate. As mentioned in our manuscript, Holbrook et al.[1] could demonstrate no deleterious effect from this approach and was able to identify 18% of high-risk subjects in premature labor by cervical examination alone. In the article by Main et al., which was cited by Dr. Arlen, there were no differences in premature rupture of membranes between those patients serially examined and the control subjects. Additionally, in the article by Lenihan, his data refer to term rather than preterm subjects. We agree with Dr. Arlen that local cervical and vaginal factors may play some role in preterm labor and premature rupture of membranes. However, as pointed out, only a limited amount of data is currently available.

Ritodrine or terbutaline—The optimal dosage in the treatment of preterm labor

To the Editors:

After reading the report by Beall et al., "A comparison of ritodrine, terbutaline, and magnesium sulfate for the suppression of preterm labor" (AM J OBSTET GYNECOL 1985;153:854-9), we would like to comment on the use of β-sympathomimetic drugs in tocolysis and especially the use of unreasonably high doses of terbutaline. Beall et al. used terbutaline in an infusion rate varying between 20 and 70 μg/min and ritodrine in a maximum dose of 350 μg/min. They present more frequent side effects when using terbutaline compared with ritodrine but otherwise similar results in terms of preventing preterm delivery.

In a recently presented double-blind study comparing ritodrine and terbutaline in the treatment for pre-

term labor, Caritis et al.[1] used maximum terbutaline infusion rates of 17.5 and 350 μg/min of ritodrine. These infusion rates correspond more closely to infusion rates used in northern Europe.

According to Swedish experience, a maximum infusion rate of terbutaline is 25 μg/min[2] although in clinical practice an infusion rate higher than 10 to 15 μg/min is rarely called for.[3]

The maternal side effects of β-mimetics are most likely correlated to the amount of drug administered.

The mechanism of β-adrenoceptor–stimulating agents has been thoroughly studied. Recently we presented a study on the down regulation of β-adrenoceptors in the myometrium after treatment of preterm labor with terbutaline.[4] In a recent study we also measured the concentration of terbutaline in plasma and myometrium from women treated with terbutaline for preterm labor and delivered with cesarean section (Berg G, Rydén G, Andersson RGG, Lindberg C. Down regulation of β-adrenoreceptors in human pregnant myometrium. Unpublished observations). We found an inverse correlation between the concentration of terbutaline in the myometrial tissue and the number of β-adrenoceptors ($r = -0.84$) indicating that the higher the dose administered, the more pronounced the degree of down regulation of the β-adrenoceptor system. Furthermore, as has also been shown by Beall et al., the higher the dosage of β-mimetics, the more frequent and probably the more severe the side effects. Equipotent doses of terbutaline and ritodrine are difficult to state, but an infusion rate of 15 to 20 μg/min of terbutaline probably better corresponds to 350 μg/min of ritodrine than does 70 μg/min of terbutaline.

In conclusion we would like to point out that massive doses of β-mimetics, whether terbutaline or ritodrine, hardly improve the results in treatment of preterm labor but certainly endanger the mother's health. When terbutaline infusion rates >20 μg/min are called for, the mechanisms triggering preterm labor must be seriously looked for and the indication for preventing a preterm birth must be thoroughly scrutinized.

[*Editorial note:* Comments on dosage were given in the reply to Caritis et al. (Beall MH, Paul RH) Am J Obstet Gynecol 1986;155:1357.]

Effect of calcium supplementation on the vascular sensitivity to angiotensin II in pregnant women

To the Editors:

Kawasaki et al. (Am J Obstet Gynecol 1985;153: 576-82) have demonstrated that calcium supplementation reduces vascular sensitivity to angiotensin II and that pregnancy-induced hypertension incidence was less (4.5%) in relation to a control group (21.2%), a difference that is statistically nonsignificant.

In the past 2 years we have been involved in a double-blinded study in which supplementation of 2 gm of elemental calcium (gluconate) was given, beginning at the twenty-fourth week of gestation until delivery, to primiparous patients, who were ≤25 years of age and normotensive at the beginning of gestation and who presented no important pathologic alterations. This study was carried out in patients who attended the prenatal clinic in the Obstetrics and Gynecology Hospital Isidro Ayora, Quito, Ecuador. We have demonstrated that pregnancy-induced hypertension, defined in the same terms as those used by the authors mentioned, was present in only 6.5% ($n = 46$) of the calcium-supplemented group. Meanwhile the incidence of pregnancy-induced hypertension in the control group, those who took placebo tablets, was 28.2% ($n = 46$), a difference statistically significant ($p < 0.001$). These results differ from that reported by Kawasaki et al., who in their study only used 156 mg of elemental calcium, in light of the fact that Belizan et al.[1] had suggested earlier the necessity of 2 gm of daily calcium supplementation to maintain constant normal levels of arterial tension during pregnancy.

The high incidence of pregnancy-induced hypertension observed in the control group could be due to known risk factors for these patients, who were primiparous and young (18.6 ± 0.7 years) and had a low daily calcium intake of approximately 300 mg. In the calcium-supplemented group, ionic calcium values, determined by calcium-specific electrode method (Nova II Biomedical, Massachusetts) was maintained constant (1.18 mmol/L ± 0.02) during the pregnancy. In the nonsupplemented group there was an important decrease of the ionic calcium concentration (1.12 ± 0.06 mmol/L) in weeks 28 and 32 of pregnancy.

On the other hand, it has been suggested that prostaglandin I_2 participates in the etiopathogenesis of pregnancy-induced hypertension.[2,3] However, the production of prostaglandin I_2 by the maternal-fetal tissues may be involved in the modulation of the pressor effect of infused angiotensin II.[4,5] We have demonstrated that extracellular calcium concentration directly affects the synthesis of prostaglandin I_2 in vascular tissue while the parathyroid hormone does not, but it can influence the generation of prostaglandin I_2 through changes in ex-

tracellular calcium levels (López-Jaramillo P, Guarner F, Moncada S. Effects of calcium and parathyroid hormone on prostacyclin synthesis by vascular tissue. Life Sci. Unpublished observations). This interesting possibility should be further studied in order to establish the mechanism by which calcium supplementation influences the behavior of blood pressure.

Cesarean sections

To the Editors:

The communique from Boylan and Frankowski (AM J OBSTET GYNECOL 1986;155:455-6), in which they suggested that the frequency of abdominal delivery be also categorized as to parity, inspired me to look closely at the comparable figures generated in our institution.

St. Mary's Hospital in San Francisco is a 550-bed community facility operated by the Sisters of Mercy. The obstetric service is about equally divided between "private" and "clinic" patients, the latter including a high percentage of individuals previously residing in Vietnam, Cambodia, and Laos. Obstetrically, the patients are ones of low- and moderate-risk status, including some who may be considered to be in the high-risk group.

From January 1, 1984, through July 31, 1986, there were 1797 deliveries at St. Mary's. Of these, 340 were delivered by cesarean section, an overall incidence of 19% (the same, in fact, as the overall rate at Hermann Hospital, where Boylan and Frankowski are located).

More pertinent to this missive, 684 of the deliveries were of patients who were para 0. This constitutes 38% of the total. The cesarean section rate in those 684 patients was 23%.

Of the remaining 1113 who were multiparous, the cesarean section rate was 17%.

The fact that there is a difference between rates of abdominal delivery at our hospital and at Hermann Hospital, when viewed by parity, is probably of no great significance. The important reality is that there is a differing section rate between primiparous and multiparous women. I would urge, as do Boylan and Frankowski, that all institutions look more closely at the occurrence of cesarean sections, with regard to the patients' parity.

Now if I may wander a bit, I have long felt that one of the reasons for the alarming increase in cesarean section rates in recent years may be the fact that an ever-expanding proportion of the obstetric population is composed of primiparous women. This fact, in and of itself, would be expected to explain some of the apparent increase in absolute rates of abdominal delivery.

Having said that, I looked back at St. Mary's obstetric population and found to my surprise that 34% of our patients in 1955 were para 0. In other words, the incidence of primiparous women at our hospital is not really much greater now than it was then. (In fact, in 1955 it was slightly higher in proportion than is Hermann Hospital's even now; 32% of all their deliveries in the first half of 1985 constituted primiparous women.)

Presumably, at least at St. Mary's, there is not truly an increasing proportion of primiparous women. That "fact" then is disqualified as a major explanation for the increasing section rate, as I had postulated earlier. (It is interesting but no surprise to those of us who go back a way that the section rate at St. Mary's in 1955 in the case of those primiparous women was only 3%. The overall rate was 4%.)

It would be of interest for other institutions to look at their "ancient" statistics in this manner.

None of these meanderings would, however, mitigate against readers segregating their cesarean section rates as to parity, as did Boylan and Frankowski.

ANNOUNCEMENT

Changes in definitions of clinical staging for carcinoma of the cervix and ovary: International Federation of Gynecology and Obstetrics

The Oncology Committee of the International Federation of Gynecology and Obstetrics at its last meeting (1985) made changes in the definition of some of the stages of carcinoma of the cervix and ovary. These changes are not in the nineteenth annual report on the results of treatment in cases of gynecologic cancer published by FIGO in 1985. Since the twentieth annual report, which will reflect these changes, will not be available until 1988, it was deemed appropriate to make this information available to the readership of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY.

The following are the changes in the definition of clinical staging for carcinoma of the cervix and ovary.

Definition of Stage I carcinoma of the cervix

Stage I. The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)

Stage IA. Preclinical carcinomas of the cervix, that is, those diagnosed only by microscopy

Stage IA1. Minimal microscopically evident stromal invasion

Stage IA2. Lesions detected microscopically that can be measured. The upper limit of the measurement should not show a depth of invasion of more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates, and a second dimension, the horizontal spread, must not exceed 7 mm. Larger lesions should be staged as IB

Stage IB. Lesions of greater dimensions than Stage IA2 whether seen clinically or not. Preformed space involvement should not alter the staging but should be specifically recorded so as to determine whether it should affect treatment decisions in the future

Notes on staging. Stage IA carcinoma should include minimal microscopically evident stromal invasion as well as small cancerous tumors of measurable size. Stage IA should be subdivided into those lesions with minute foci or invasion visible only microscopically as Stage IA1 and the macroscopically measurable microcarcinomas as Stage IA2 in order to gain further knowledge of the clinical behavior of these lesions. The term IB occult should be omitted.

The diagnosis of both Stage IA1 and IA2 should be based on microscopic examination of removed tissue, preferably a cone, which must include the entire lesion. As noted above, the lower limit of Stage IA2 should be that it can be measured macroscopically (even if dots need to be placed on the slide before measurement) and the upper limit of IA2 is given by measurement of the two largest dimensions in any given section. The depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates. The second dimension, the horizontal spread, must not exceed 7 mm. Vascular space involvement, either venous or lymphatic, should not alter the staging but should be specifically recorded as it may affect treatment decisions in the future.

Lesions of greater size should be staged as IB.

As a rule, it is impossible to estimate clinically whether a cancer of the cervix has extended to the corpus. Extension to the corpus should therefore be disregarded.

Stage grouping for primary carcinoma of the ovary

These categories are based on findings at clinical examination and/or surgical exploration. The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.

Stage I. Growth limited to the ovaries

Stage IA. Growth limited to one ovary; no ascites. No tumor on the external surface; capsule intact

Stage IB. Growth limited to both ovaries; no ascites. No tumor on the external surfaces; capsules intact

Published with the permission of FIGO.

Stage IC.* Tumor either Stage IA or IB but with tumor on the surface of one or both ovaries; or with capsule ruptured; or with ascites present containing malignant cells or with positive peritoneal washings

Stage II. Growth involving one or both ovaries with pelvic extension

Stage IIA. Extension and/or metastases to the uterus and/or tubes

Stage IIB. Extension to other pelvic tissues

Stage IIC.* Tumor either Stage IIA or IIB but with tumor on the surface of one or both ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells or with positive peritoneal washings

Stage III. Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastasis equals Stage III. Tumor is limited to the true pelvis but with histologically verified malignant extension to small bowel or omentum

Stage IIIA. Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces

Stage IIIB. Tumor of one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter. Nodes negative

Stage IIIC. Abdominal implants >2 cm in diameter and/or positive retroperitoneal or inguinal nodes

Stage IV. Growth involving one or both ovaries with distant metastasis. If pleural effusion is present there must be positive cytologic test results to allot a case to Stage IV. Parenchymal liver metastasis equals Stage IV

*In order to evaluate the impact on prognosis of the different criteria for allotting cases to Stage IC or IIC it would be of value to know if rupture of the capsule was (1) spontaneous or (2) caused by the surgeon and if the source of malignant cells detected was (1) peritoneal washings or (2) ascites.

Corrections

In the article by Hadgu et al., entitled "Predicting acute pelvic inflammatory disease: A multivariate analysis" (Am J Obstet Gynecol 1986;155:954-60), on page 958 under the heading "Prediction outside estimation data," the 500 observations referred to in the second sentence should have read 599 observations.

In the article by Krebs, entitled "Intestinal injury in gynecologic surgery: A ten-year experience" (Am J Obstet Gynecol 1986;155:509-14), in Table II, on page 511, under the heading "Adnexal disease," Total No., given as 1450, should have been 1920; Small bowel %, given as 1.0, should have been 0.7; Large bowel %, given as 0.6, should have been 0.4; Total %, given as 1.5, should have been 1.1.

Roster of American obstetric and gynecologic societies*

(Appears annually in the January issue)

American Board of Obstetrics and Gynecology, Inc. (1930) *President,* Daniel R. Mishell, Jr. *Executive Director,* James A. Merrill, 4507 University Way, N.E., Seattle, WA 98105. Meeting, December 7-11, 1987.

II Panamerican Symposium on Perinatal Medicine, Hotel Miramar, Viña del Mar, Chile, April 8-11, 1987. For further information contact: Organización TRES Ltda., Ms. Marcela Torres, Casilla 16522, Correo 9, Santiago, Chile. Telex: 340436 PB VTR CL Tres Ltda. Tel.: 2319103-2318211.

Contemporary Obstetrics and Neonatology: Partners in Prematurity, February 25-27, 1987, Doubletree Hotel, Orange, California. Sponsored by the University of California, Irvine, College of Medicine, Division of Neonatal/Perinatal Medicine. For further information contact: Mari Jo Craft, RNC, Program Director, University of California, Irvine, Medical Center, 101 City Dr., Route 81, Orange, CA 92668. Tel.: (714) 634-6162.

COMMUNITY HEALTH CENTER
Westchester County, New York

Seeking OB/GYN specialist due to expansion of services of established Community Health Center located 30 miles north of New York City. Board certified or eligible. Beautiful facility, excellent hospital affiliations, good benefits, including malpractice insurance. Full-time or Part-time beginning early 1987. Salaried. Spanish language helpful. Equal Opportunity Employer.

Submit C.V. to

K. Thompson
Administration
6 Furnace Street
Cold Spring, NY 10516

PERINATOLOGIST
Denver, Colorado

Rose Medical Center, Denver, Colorado, is seeking a BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3600 deliveries per year, and thirty-six University residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities would include private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Medicine division at the University of Colorado and would be eligible for an appropriate clinical appointment at the University.

A competitive salary guarantee is being offered with excellent fringe benefits including malpractice insurance.

Qualified applicants, including individuals completing fellowship in June, 1987 should forward CV's to:

Robert E. Wall, M.D.
Chairman, Department of OB/GYN
Rose Medical Center
4567 E. Ninth Avenue
Denver, Colorado 80220

REPRODUCTIVE ENDOCRINOLOGIST

Pennsylvania Hospital seeks Board Certified or eligible specialist with fellowship training in reproductive endocrinology and infertility. Responsibilities include participation in IVF program, resident and medical student education and active clinical practice. Appointment is at the Assistant Professor level. Previous experience in academic medicine is desirable.

Pennsylvania Hospital is an affiliate of the University of Pennsylvania and is an Affirmative Action Equal Opportunity Employer.

Interested candidates should send curriculum vitae to:

Esther Eisenberg, M.D.
Department of Obstetrics and Gynecology
Pennsylvania Hospital
Eighth and Spruce Streets
Philadelphia, PA 19107

Subspecialist Positions

615-bed tertiary care facility is seeking several board eligible or board certified subspecialists for the following areas within an expanding Department of Obstetrics and Gynecology.

- **Maternal/Fetal Medicine**
  Two new positions available in our established division of Maternal/Fetal Medicine. Ultrasound experience desirable.
- **Reproductive Endocrinology**
  An exceptional growth opportunity is available for a physician to direct this new division.

These positions offer excellent opportunities for professional development to qualified physicians interested in subspecialty practice, resident training, and research/faculty status in a large university affiliated hospital.

SINAI HOSPITAL OF DETROIT

Please submit your Curriculum Vitae or contact **Dr. David B. Schwartz, Chairman, Department of Obstetrics and Gynecology, Sinai Hospital of Detroit, 6767 W. Outer Drive, Detroit, MI 48235, or call (313) 493-5220.**

GYNECOLOGIC ONCOLOGIST

The Allentown Hospital, with the 5th largest obstetrical service in Pennsylvania, is actively seeking a board certified or board eligible gynecologic oncologist for private practice and to provide leadership and medical education in gynecologic oncology.

The Hospital, a component of the HealthEast System, is located in the very desirable Lehigh Valley, in close proximity to all major East Coast cities. It sponsors a fully accredited OB/GYN residency program and has a major medical school affiliation. The Hospital co-sponsors a Comprehensive Community Cancer Center and offers a special interest gynecology group from multi-disciplinary specialties. There are no Board certified or Board eligible gynecologic oncologists in the Lehigh Valley, and the position provides a superb opportunity to establish a subspecialty practice and be integratly involved in a major regional teaching program.

Submit C.V. in complete confidence to:

Sze-ya Yeh, M.D.
Chairman, Department of Obstetrics/Gynecology
The Allentown Hospital
17th & Chew Streets
Allentown, Pennsylvania 18102

LAPAROSCOPIC COMPLICATIONS: Prevention and Management

By Max Borten, M.D.
Written by a recognized authority, this book gives you first-hand knowledge on both medical and surgical management of laparoscopic complications. From indications and contraindications, it guides you through detailed discussions of failures of procedure and equipment, to the medicolegal aspects of both the procedure and its complications. Intraoperative slides and line drawings fully illustrate the text. Once you see it, you won't let it go! Order your copy today! 1986. 464 pages. (D-0723-X) Mosby distributes this B.C. Decker, Inc. publication. About $79.50

OUTLINE OF CONTENTS: INTRODUCTION: Instrumentation, Technique, Diagnostic Indications for Laparoscopy, Operative Indications for Laparoscopy, Laparoscopic Sterilization, Contraindications to Laparoscopy, Nongynecologic Indications for Laparoscopy, Choice of Anesthesia, Circulatory Changes, Respiratory Changes, Postoperative Recovery COMPLICATIONS: Equipment Failure, Procedural Failure, Complications of Anesthesia, Complications of Pneumoperitoneum, Complications of Trocar Insertion, Vascular Injuries, Intestinal Tract Injuries, Urinary Tract Injuries, Tegumentary Injuries, Complications due to Infection, Complications of Sterilization, Electrical Complications, Postoperative Complications, Medicolegal Aspects of Laparoscopy APPENDIX: Translaparoscopic Photography

Tablets

Enhanced patient compliance

(norethindrone/ethinyl estradiol)

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

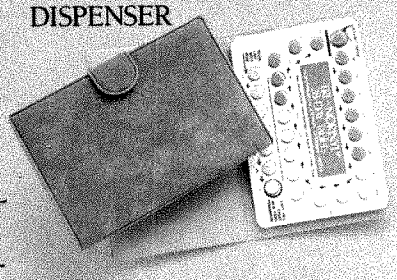
UNIQUE

Full-cycle endometrial support, with no late-cycle progestin increase.

The unique TRI-NORINYL phasing achieves BTB control equivalent to a 1/35 formulation, but with 29% less progestin per cycle. This is, in fact, the greatest progestin reduction of any norethindrone-based multiphasic. TRI-NORINYL lowers progestin where requirements for endometrial support are reduced—with no greater reported BTB than a 1/35 formulation.*

9 DAYS 1.0 MG NORETHINDRONE



7 DAYS 0.5 MG NORETHINDRONE

5 DAYS 0.5 MG NORETHINDRONE

21 DAYS 0.035 MG ETHINYL ESTRADIOL

PILL DAYS

SUPPLIED IN THE EXCLUSIVE SYNTEX WALLETTE™ PILL DISPENSER

Preferred by patients 3 to 1 over other available packages for convenience, discreetness and compliance.**

THE NATURE OF TRI-NORINYL

*1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. Data available from Syntex Laboratories, Inc.

**Based on a nationwide, independently conducted survey of prospective oral contraceptive patients. Data available from Syntex Laboratories, Inc.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema, or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests *Chlamydia trachomatis* infection, the leading cause of nongonococcal P.I.D., is enhanced by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease) change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

PALO ALTO, CA 94304

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

Mycelex® Twin Pack
(clotrimazole)

One-day therapy
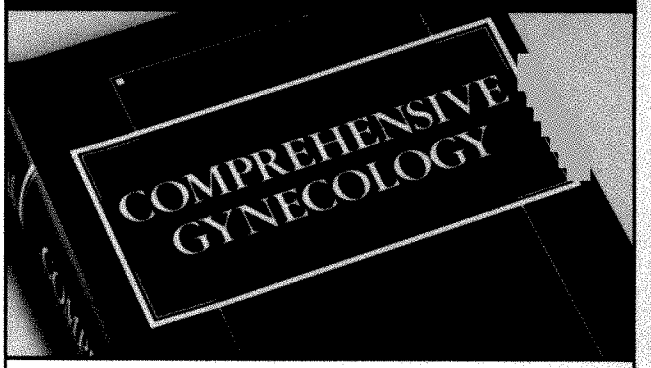
Mycelex®-G 500mg
(clotrimazole) Vaginal Tablet

Seven-day therapy
Mycelex® 1%
(clotrimazole)
Cream



Indications
MYCELEX®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one-day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended.
MYCELEX® CREAM is indicated for the topical treatment of dermal infections due to *Candida albicans*.
Contraindications
MYCELEX-G 500 mg Vaginal Tablets and MYCELEX CREAM are contraindicated in women who have shown hypersensitivity to any of their components.
Warnings
MYCELEX-G 500 mg Vaginal Tablets: none. MYCELEX CREAM is not for ophthalmic use.
Precautions
MYCELEX-G 500 mg Vaginal Tablets: If there is a lack of response to the Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.
MYCELEX CREAM: If irritation or sensitivity develops with the use of Mycelex Cream, treatment should be discontinued and appropriate therapy instituted.
Carcinogenesis
MYCELEX-G 500 mg Vaginal Tablets: No long-term studies in animals have been performed to evaluate the carcinogenic potential of 500 mg Vaginal Tablets intravaginally. A long-term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.
Usage in Pregnancy: Pregnancy Category B:
MYCELEX-G 500 mg Vaginal Tablets: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.
In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy.
Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.
MYCELEX CREAM: In the first trimester of pregnancy, Mycelex Cream should be used only when considered essential to the welfare of the patient.
Adverse Reactions
MYCELEX-G 500 mg Vaginal Tablets: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.
MYCELEX CREAM: The following reactions have been reported in connection with the use of this cream: erythema, stinging, blistering, peeling, edema, pruritus, urticaria, and general irritation of the skin.

Innovation Plus Expertise!

COMPREHENSIVE GYNECOLOGY

By William Droegemueller, M.D.; Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; and Morton A. Stenchever, M.D.

Innovative enough to emphasize the psychosocial treatment of your patient, with the expertise to cover a full range of diseases and physical problems — this combination brings you the first, all new comprehensive gynecology text in years! Comprehensive discussions on:

- the most current treatments available
- psychosocial approaches to the troubled patient
- family planning and pregnancy termination
- breast disease and sexually transmitted diseases, including AIDS in women
- rape, incest and other physical abuse

The Key Terms and Definitions that begin each chapter and the synopsis of Key Points at the end provide a quick review. Sophisticated graphics highlight pertinent data. Written by four well-known specialists who share their experience and expertise, COMPREHENSIVE GYNECOLOGY presents state-of-the-art information you'll refer to again and again.

July, 1987. Approx. 1,000 pages with 800 illustrations. (Book Code: 01929) About $60.00 (U.S.); $82.95 (Can.)

Hemoglobin determination, traditional procedures.

Traditional in-office Hb testing involves messy reagents, pipettes, test tubes, etc – not to mention instrument calibration and zero setting. A complex and time consuming procedure with high error potential, especially in the dispensing of blood and reagents.

Or take hematocrit where errors can arise from incorrect centrifuge speeds. And more to the point, why measure hematocrit when it is the Hb value that defines anemia?

And what if you use an outside laboratory instead? When the test results finally arrive the patient has long since left your office. The case record has to be extracted again, the patient contacted and perhaps recalled.

The new 60-second HemoCue procedure.

1. *Obtain a blood sample by finger stick.*

2. *The HemoCue microcuvette draws an exact amount of blood.*

3. *Insert the microcuvette into the HemoCue photometer.*

4 *Result displayed automatically within*

The secret of the HemoCue Hb test system lies in the unique disposable microcuvette, which serves as pipette, test tube and measuring vessel in one. Containing a dry reagent it self-fills with blood by capillary action to produce a precise chemical reaction.

The HemoCue photometer is fully automated. The only control is the ON/OFF switch! No liquid reagents are used. Zero setting and functional adjustments are performed automatically between tests. It also automatically compensates for turbidity in the sample!

Thanks to HemoCue you can now get **accurate** Hb test results, truly stat, while the patient is still in your office.

For more information on this new and economical test, call 800-323-1674 (CA 714-859-7779).

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

FAST, SOOTHING RELIEF
Complete coverage–
and minimal vaginal leakage![1]

3-DAY THERAPY
As effective as miconazole cream–
in only 3 days' time!

3 DISPOSABLE APPLICATORS
Patient convenience and satisfaction–
for enhanced compliance!

*In non-pregnant patients, 3-day treatment is recommended. Treatment may be extended an additional 3 days, if necessary.

1. Droegemueller W, Adamson DG, Brown D et al: Three-day treatment with butoconazole nitrate for vulvovaginal candidiasis. *Obstet Gynecol* 64:530-534, 1984.

Please see brief summary of prescribing information on next page.

The Only 3-Day Cream*

Think

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

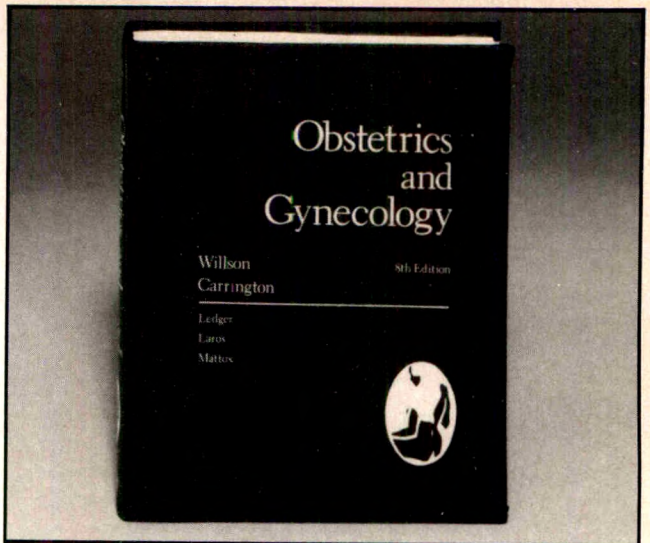
Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.



CAUTION:
Federal law prohibits dispensing without prescription.

New 8th Edition! OBSTETRICS AND GYNECOLOGY

Edited by J. Robert Willson, M.D. and Elsie Reid Carrington, M.D.; Associate Editors Russell K. Laros, Jr., M.D.; William J. Ledger, M.D.; and John H. Mattox, M.D.; with 4 contributors.

In a review of the 7th edition, JAMA said that it "maintains excellence especially in general obstetrics" and "fulfills its purpose as a useful text for various levels of students of obstetrics and gynecology." This new edition, with the addition of two new editors, continues the tradition! Emphasis is on treatment of the "total woman," following the normal life-cycle—birth through pregnancy.

- easy-to-read format facilitates Board review
- a new chapter on androgen disorders
- infertility, endocrinology and endometriosis
- ectopic pregnancy, abortion and infectious disease
- radiologic studies in pregnant women

April, 1987. Approx. 768 pages, 562 illustrations. (Book Code: 05650) About $44.95 (U.S.); $62.25 (Can.)

- Decreased total cholesterol; increased HDL cholesterol; lowered LDL cholesterol
- Easy cycling with progestin
- Unsurpassed long-term safety

PREMARIN®

Complete estrogen therapy

Please see following page for brief summary of prescribing information.

The appearance of PREMARIN Tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR.)*

PREMARIN® Brand of conjugated estrogens tablets, USP

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens tablets, USP) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens.

INDICATIONS AND USAGE: Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown th there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer ar women for postpartum breast engorgement. Users of oral contraceptives have an increased ris of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarctio Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported oral contraceptive users. An increased risk of postsurgery thromboembolic complications ha also been reported in users of oral contraceptives. If feasible, estrogen should be discontinue at least 4 weeks before surgery of the type associated with an increased risk of thromboen bolism, or during periods of prolonged immobilization. Estrogens should not be used in persor with active thrombophlebitis, thromboembolic disorders, or in persons with a history of suc disorders in association with estrogen use. They should be used with caution in patients wi cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day comparable to those used to treat cancer of the prostate and breast have been shown t increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebiti When doses of this size are used, any of the thromboembolic and thrombotic adverse effec should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pa and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has bee reported in women taking estrogen-containing oral contraceptives. Increased blood pressu may occur with use of estrogens in the menopause and blood pressure should be monitore with estrogen use. A worsening of glucose tolerance has been observed in patients c estrogen-containing oral contraceptives. For this reason, diabetic patients should be careful observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bor metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should b taken prior to the initiation of any estrogen therapy with special reference to blood pressur breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a gener rule, estrogen should not be prescribed for longer than one year without another physic examination being performed. Conditions influenced by fluid retention, such as asthma, ep lepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patien may develop manifestations of excessive estrogenic stimulation, such as abnormal or exce sive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estroge therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Or contraceptives appear to be associated with an increased incidence of mental depressio Patients with a history of depression should be carefully observed. Pre-existing uterin leiomyomata may increase in size during estrogen use. The pathologist should be advised estrogen therapy when relevant specimens are submitted. If jaundice develops in any patie receiving estrogen, the medication should be discontinued while the cause is investigate Estrogens should be used with care in patients with impaired liver function, renal insufficienc metabolic bone diseases associated with hypercalcemia, or in young patients in whom bon growth is not yet complete. If concomitant progestin therapy is used, potential risks may includ adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increase norepinephrine-induced platelet aggregability.

c. Increased thyroic binding globulin (TBG) leading to increased circulating total thyroi hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptak is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done on when clearly necessary since mar drugs are excreted in human milk.

Long-term, continuous administra tion of natural and synthetic estr gens in certain animal species ir creases the frequency of carcinoma of the breast, cervix, vagina, and live However, in a recent, large case-cor trolled study of postmenopausa women there was no increase in ris of breast cancer with use of conju gated estrogens.

ADVERSE REACTIONS: The fo lowing have been reported with es trogenic therapy, including oral cor traceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; pre menstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterin fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secre tion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persis when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses headache, migraine, dizziness, mental depression, chorea; increase or decrease in weigh reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short-term use only.* For treatmer of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associate with the menopause (0.3 mg to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should b discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals

2. *Given cyclically:* Osteoporosis. Female castration.

Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and on week off).

Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to re sponse of the patient. For maintenance, adjust dosage to lowest level that will provide effectiv control.

Patients with an intact uterus should be monitored for signs of endometrial cancer an appropriate measures taken to rule out malignancy in the event of persistent or recurrin abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology.* The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manu-

script and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

Cefizox® IM IV

brand of sterile

ceftizoxime sodium

ase see brief summary of prescribing
ormation on last page of this advertisement.

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR.* The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae.* 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients w developed diarrhea in association with antibiotic use. Treatment with broad-spectrum antibioti alters normal flora of the colon and may permit overgrowth of *Clostridia.* Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro.* Mild cases o colitis may respond to drug discontinuance alone. Moderate to severe cases should be manag with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for an biotic-associated pseudomembranous colitis produced by *C. difficile.* Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution i individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Car ful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There ar however, no adequate and well-controlled studies in pregnant women. Because animal reprodu tion studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established

Nursing Mothers: 'Ceftizox' is excreted in human milk in low concentrations. Caution should l exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not bee established. In children six months of age and older, treatment with 'Cefizox' has been associat with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phosphokinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, b less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGC SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elev tions of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*-Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomitir have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxin

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufacture for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

Psychological characteristics of in vitro fertilization participants

M. T. Hearn, Ph.D., A. A. Yuzpe, M.D., S. E. Brown, M.D., and R. F. Casper, M.D.

London, Ontario, Canada

Psychological characteristics of couples attending an in vitro fertilization clinic were examined. Participants completed measures of personality, family environment, life quality, coping, and emotional status. Couples seeking in vitro fertilization exhibited specific personality traits and cohesive, supportive relationships. Unexpectedly, they reported good quality of life and freedom from anxiety and depression. (AM J OBSTET GYNECOL 1987;156:269-74.)

Key words: In vitro fertilization, psychological characteristics of participants

Since the first successful intrauterine pregnancy in 1979, hundreds of pregnancies have been reported worldwide as a result of in vitro fertilization and embryo transfer procedures. Most of the literature on this procedure is focused on the medical aspects of the in vitro fertilization procedure, which has moved rapidly from an experimental technique to a successful medical treatment for some forms of infertility. Some concern about the psychological aspects of in vitro fertilization has accompanied the development of in vitro fertilization treatment programs.[1, 2] Some authors[3, 4] have emphasized the need for psychological screening to single out those applicants for whom an in vitro fertilization attempt might be emotionally contraindicated. Some[1-5] have emphasized the need for psychological support, and others[5, 6] have investigated the degree of dysfunctional emotional distress shown by in vitro fertilization participants. Few studies have investigated the psychological characteristics of couples seeking in vitro fertilization, and thus far there is little known about the psychological and emotional states of couples entering in vitro fertilization programs. This lack of information makes it difficult to plan adequate support systems for couples entering in vitro fertilization programs.

This article describes the psychological characteristics of couples entering an in vitro fertilization treatment program in a university teaching hospital and discusses briefly the type of support procedures that would complement participants' needs. These pretreatment assessment data also represent a baseline for future study of couples who complete a successful pregnancy as a result of an in vitro fertilization attempt in comparison with couples who are unsuccessful.

Material and methods

Criteria. Couples entering the in vitro fertilization treatment program were required to meet the following criteria: (1) a stable marital relationship; (2) age of 40 years or under; (3) evidence of tubal disease, which might include failed tubal surgery, surgical repair with <10% chance of pregnancy, or absent fallopian tubes; (4) sperm count in the husband within the normal fertile range; and (5) exhaustion of other attempts to restore fertility.

Sample selection. The sample comprised 300 couples who were consecutive admissions to the in vitro

fertilization treatment program during an 18-month period between January 1984 and July 1985.

Measures. The following psychological self-report measures were used.

The Family Environment Scale[7] measures the social-environmental characteristics of families, and there are 10 subscales. Scores on the subscales indicate an individual's perception of the conjugal or nuclear family environment.

The Personality Research Form-E[8] measures personality characteristics of individuals, and there are 20 content scales and two validity scales. Scores on the content scales indicate an individual's style of normal functioning on traits such as autonomy, nurturance, and endurance.

The Quality of Life Questionnaire[9] assesses an individual's functional behavior in response to several ecologic domains. Major domains assessed include general well-being, interpersonal relations, organizational activity, occupational activity, and leisure-recreational activity.

The Life Satisfaction Questionnaire[10] yields a score

†$p < 0.01$.

on a one-item rating scale measuring satisfaction with life in general.

The Life Appraisal Inventory[10] results in an affect balance score representing the degree of affect, along a positive-negative continuum, associated with an individual's life.

The Inventory of Socially Supportive Behaviors[11] measures the frequency of socially supportive contacts.

The Ways of Coping Checklist (Revised)[12] provides information concerning the strategies an individual uses to cope with a specific stressful life event.

The State-Trait Anxiety Inventory[13] measures two distinct anxiety concepts. The state anxiety scale yields a measure of how a subject feels at a particular moment in time, as opposed to the trait anxiety scale, which measures how a subject feels in general.

The Beck Depression Inventory[14] measures an individual's current level of depression.

Demographic information and reasons for wanting a child were also solicited.

Procedure. On meeting the medical criteria and approximately 3 months before the first visit to the in vitro fertilization clinic, prospective couples were sent two packages of the above inventories. In an explanatory letter, husband and wife were requested to complete a single package of inventories independently and to return these to the program. The questionnaires were scored and used as both a data base and a source of information for the clinical interview. On assessment day, couples were engaged in a structured interview designed to assess their attitudes to and preparation for the in vitro fertilization program. Interpretation of the assessment information was undertaken, concerns about psychological responses to the in vitro fertilization process were discussed, and, where appropriate, improved modes of coping were considered. Another use of the interview was to substantiate the questionnaire data. As there was high concordance for all participants between questionnaire and interview responses, no data were excluded because they were questionable.

Results

Characteristics of the sample. The mean age of the group was 32 years and the socioeconomic status of the group was 5.5 on the Hollingshead scale of social status (Hollingshead AB. Four factor index of social status. New Haven: Department of Sociology, Yale University, 1975, unpublished manuscript.). A mean income of $40,000 was reported for couples. Thirty-five percent of the group reported education beyond high school, of which 15% graduated from a university. Overall, the mean educational level of the group was completion of grade 12. Twenty-six percent of the group reported themselves as Protestant in their religious preference, 26% Catholic, 1% Jewish, and 49% other or none.

Table V. Means and standard deviations for the in vitro fertilization group on coping and social support measures

Scale	*Mean*	*SD*
Ways of coping		
Problem-focused coping	13.08	6.65
Wishful thinking	5.22	3.42
Distancing	4.85	3.04
Seeking social support	8.69	4.58
Emphasizing the positive	5.05	2.87
Self-blame	1.34	1.68
Tension reduction	1.52	1.55
Self-isolation	1.98	1.84
Inventory of socially supportive behaviors	79.80	18.52

Twenty percent of the group had been previously married and divorced, and 1% was widowed. Couples reported a mean of 0.4 children for their current relationship and 0.3 for a previous relationship. This compares with a national average of 1.3 children per couple. In order of priority, couples endorsed the following as important reasons for wanting a child: strong desire, 82%; belief in their own ability to provide good parenting, 64%; desire of spouse for a child, 58%; and life incomplete without children, 33%.

Family environment. Compared with the normative sample for the Family Environment Scale, the in vitro fertilization couples indicated significantly greater organization, cohesion, expressiveness, and a stronger moral-religous emphasis in their relationship (see Table I). In contrast they reported significantly lower levels of conflict, control, and intellectual-cultural orientation.

Personality. Women and men in the in vitro fertilization group, in comparison with the normative sample of the Personality Research Form-E, reported a significantly higher need for cognitive structure, harm avoidance, nurturance, and order (see Tables II and III). Conversely they indicated a significantly lower need for autonomy, change, play, sentience, and understanding. Both women and men responded to the Personality Research Form-E in a more socially desirable manner.

Quality of life. Couples in the in vitro fertilization group did not differ from the North American normative sample in overall life satisfaction, general affect, or overall well-being. On the more specific Quality of Life Questionnaire they reported higher levels of personal growth, marital relations, extended family relations, extrafamilial relations, job characteristics, job satisfiers, and vacation behavior than the normative group (see Table IV). Again, increased social desirability bias in responding was observed.

Coping and social support. Comparable normative data for the coping and social support measures were not available. The means and standard deviations for these measures are shown in Table V. That coping and social support activities are effective is demonstrated by the fact that men and women in the in vitro fertilization group do not differ from normal samples with respect to depression (see Table VI). With respect to anxiety the women do not differ from the normative sample, and the men are significantly less trait and state anxious than the normal sample.

Comment

The findings of this investigation relate to an organic sample only; hence they cannot be generalized to all in vitro fertilization candidates. As well, respondents

Table VI. Comparison of women and men in the in vitro fertilization group with the normative data for the State-Trait Anxiety Inventory

†$p < 0.05$.

evidenced some bias toward socially acceptable responding, possibly because of their concern that they be psychologically acceptable for an in vitro fertilization program. A further limitation in the interpretation of the current findings is the lack of a relevant control group. However, definition of a control group for an in vitro fertilization population is difficult in that few other stressful life events: (1) continue for the length of time encompassed by an infertility problem, (2) have a comparable probability of success, and (3) involve an invasive procedure. Finally the data for coping and social support are included for descriptive purposes only, as these instruments lack normative data at this time. Despite these limitations, the investigation of psychological characteristics of in vitro fertilization couples reveals information about the functioning of these couples, and this can be utilized in developing support programs to complement their emotional needs.

In this study couples presenting for in vitro fertilization–embryo transfer treatment exhibited closer marital relationships, a more conservative approach to life, a higher quality of life, and emotional adjustment and coping comparable to that of a normal population. Many of these couples have attempted resolution of their infertility during a period of many years. Hence it is possible that the characteristics and coping strategies they exhibit result from their experiences in seeking resolution of their infertility.

The marital relationship of these couples is one of openness, support, and warmth, with clear lines of marital organization and little concern about control. Although considerable attention has been given to the negative effects of infertility,[15] this has not been accompanied by investigation of the positive aspects of those relationships that survive infertility. It is conceivable that as a result of confronting their infertility couples develop a fuller, richer relationship that can be utilized as a source of strength during an in vitro fertilization treatment.

Couples entering in vitro fertilization programs have been investigated for psychopathologic conditions and there is evidence that these exist.[5, 6] However, the majority of couples entering an in vitro fertilization program will present with normal personality functioning. While some programs may wish to screen for this, the low level of psychopathologic findings in the current sample (1%) suggests that concentration on personality styles and coping mechanisms rather than psychopathologic conditions may prove more profitable in assisting couples to cope with stress as they proceed through an in vitro fertilization program. In the current study, couples undergoing in vitro fertilization presented as serious individuals with high needs for orderly, predictable, threat-free environments that offer them opportunity for support.

Since many aspects of the in vitro fertilization attempt are unpredictable (medication response, egg retrieval, fertilization, and outcome), it is likely that many of these couples will find themselves in an environment that is not complementary to their personality needs. To rectify this, in vitro fertilization programs could provide couples with accurate and adequate information about what might occur at any and every stage of the in vitro fertilization process. The degree to which a program provides structure through information meetings, audio-video tapes, literature, and availability of well-trained staff may well determine the degree of stress that couples experience as they proceed through an in vitro fertilization program.

The findings from the Quality of Life Inventory indicate that, despite the lack of fulfillment of their desire for children, infertile couples develop an above-average quality of life. Possibly the time and expense that would otherwise be expended on children are directed

toward activities that are personally rewarding and meaningful.

Normal depression and anxiety levels were unexpected in this population, in view of the distress that has been attributed to infertility[15] and the stress that is associated with the in vitro fertilization treatment. The participants in this study showed low levels of depression that were comparable to those of the nonpregnant women and nonexpectant men in the Canadian sample studied by Lips.[16] Given the anticipation of a potential solution to their infertility problem, a lack of depression in this population is reasonable before entry into the program. When compared with participants in the study of Dennerstein and Morse,[17] women in the present organic sample showed lower levels of both trait and state anxiety than their organic and idiopathic groups. In the current study, the sample size and participation rate suggest that it is appropriate to conclude that 3 months before entry into the program trait and state anxiety are within normal limits for women seeking in vitro fertilization for organic reasons. In the study by Dennerstein and Morse,[17] high levels of anxiety were reported for the organic and idiopathic groups. However, it is unclear whether these levels of anxiety differed significantly from those of the normative sample. Further, their small sample size and method of sampling may have resulted in atypical groups. This possibility is partially supported by the fact that their female sample was characterized by a long history of hospitalizations extending back to childhood and a 26% rate of previous psychiatric involvement. These were not the characteristics of the current sample. It is important, however, to note that couples completed the questionnaires for the current study 3 months before their entry into the program. It is possible that anxiety levels might have increased by the time of the actual attempt.

The use of problem solving as a coping strategy has been associated with normal levels of emotional responsivity,[12] and certainly problem solving was endorsed as a prime coping strategy by in vitro fertilization participants in this study. However, recent research on coping and emotions indicates the need to view these variables as process rather than static variables.[12] Thus further research is needed to evaluate both coping strategies and emotional levels of in vitro fertilization participants as they proceed through in vitro fertilization attempts.

Couples who enter in vitro fertilization programs are more likely to face negative outcomes than positive ones and therefore will be required to cope with the emotional distress associated with a negative outcome. On the basis of experience with the current program, identification of psychological characteristics of in vitro fertilization participants permits the development of appropriate programming and staff support. As well, knowledge of psychological characteristics of this population may result in a better understanding of why some couples undergoing in vitro fertilization proceed to a successful pregnnacy but others do not.

Detecting changes in functional ability in women with premenstrual syndrome

Barbara W. Posthuma, O.T.(C), M.Ed., Martin J. Bass, M.D., Shelley B. Bull, Ph.D., and Jeffrey A. Nisker, M.D.

London, Ontario, Canada

There has been a lack of objective assessment of the disruptive effect that the symptomatology of premenstrual syndrome has on the functional performance of affected women. This study assessed the functional performance of women with premenstrual syndrome at four phases of the menstrual cycle. Twelve women with premenstrual syndrome and nine asymptomatic women were tested on four functional instruments at the menstrual, early follicular, early luteal, and late luteal phases. Two tests of a paper-and-pencil type measured perceptual parameters, and two tests involving manipulation of objects measured manual dexterity. Mean performance on the Crawford Small Parts Dexterity Test—Part II, which tests fine motor function, was better at the late luteal testing, compared to the early follicular testing, in asymptomatic women but was worse in the women with premenstrual syndrome. This difference was statistically significant ($p = 0.015$). No significant differences between groups in performance changes were observed for the other functional tests. The Crawford Small Parts Dexterity Test–Part II is an objective measure that is potentially valuable in therapeutic trials involving patients with premenstrual syndrome. (Am J Obstet Gynecol 1987;156:275-8.)

Key words: Premenstrual syndrome, functional abilities, manual dexterity

Women with premenstrual syndrome experience both psychological and somatic symptomatology.[1] The question has been raised whether such symptoms may impact on the ability of women to function in the work place.[2] Certain functional abilities have been assessed throughout the menstrual cycle in normal women.[3-5] Although significant cyclic changes were not found in reaction times, Kopell et al.[5] observed that time estimation varied significantly and Stocker[6] found variability in fine and gross motor performance in normal women over the menstrual cycle. The present study was conducted to identify a test that objectively measured changes in functional ability and then to compare the functional ability of women with premenstrual syndrome to that of unaffected women.

Subjects and methods

Subjects who were recruited through newspaper and bulletin board advertisements as well as physician referral were required to meet the following initial criteria: (1) were 28 to 40 years of age; (2) had at least one viable pregnancy; (3) were not taking medications; (4) were free of any manual handicap; (5) had regular menstrual cycles of 26- to 30-day intervals. Then, with use of a symptom questionnaire, subjects rated their emotional symptoms (weepy, depressed, lose temper, irritable, bitchy) and their somatic symptoms (headache, fatigue, bloating, breast swelling, cramping, pain) from absent to marked on a four-point scale throughout the menstrual cycle. Women who experienced moderate or severe symptoms (ratings of 2 or 3) in the luteal phase; which markedly diminished with the menses (ratings of 0 or 1), were considered to be potential premenstrual syndrome subjects. Women with mild or absent symptoms throughout the cycle (ratings of 0 or 1) were accepted as potential control subjects.

To further verify the diagnoses of premenstrual syndrome, all subjects kept a daily diary, recording symptoms and basal body temperatures over two complete menstrual cycles. All diaries were then reviewed in a blinded fashion by one of us (J. A. N.), who categorized the subjects as definitely having premenstrual syndrome, definitely not having premenstrual syndrome, or uncertain. During these 2 months 12 of 28 potential premenstrual syndrome subjects consistently rated their symptoms throughout predictable ovulatory menstrual cycles as marked or severe in the late luteal phase and as absent or mild immediately following the onset of menses. These 12 subjects were then accepted with reasonable assuredness as having premenstrual syn-

drome. The accepted premenstrual syndrome subjects all demonstrated both somatic and psychological symptoms, at least one of which was rated as severe. Of 15 potential control subjects, nine who had consistently recorded absent or mild symptoms throughout predictable ovulatory menstrual cycles were considered to be free of premenstrual syndrome and were accepted as controls.

Four functional instruments were chosen for assessment. The MacQuarrie Test for Mechanical Ability[7] and the Revised Minnesota Paper Form Board[8] are paper-and-pencil tests that measure perceptual parameters. The Crawford Small Parts Dexterity Test[9] and the Minnesota Rate of Manipulation Test[10] require subjects to handle objects singly or in combination and measure manual dexterity. All these tests have been standardized, and norms are available for many groups.

Subjects completed all four tests at four specific phases over the menstrual cycle: (1) initial menstruation, days 3 to 5; (2) early follicular, days 6 to 9; (3) early luteal, days 17 to 21; (4) late luteal, days 25-28; they then had a second menstrual assessment. Two different orders of the four test presentations were established and assigned in turn within each group. The tester was blind to the status of each subject.

A general framework for analysis was provided by the repeated-measures analysis of variance model.[11, 12] This model permitted comparison of the two groups with respect to changes between menstrual phases while taking into account the fact that measurements were repeated on each subject on several occasions. The relative magnitude of individual variance as expressed in the intraclass correlation coefficient provided an estimate of reliability.[12] The model assumptions of sphericity were also confirmed.[13] There was no evidence of order effects.

Results

Of the four instruments investigated, only the Crawford Small Parts Dexterity Test showed a significant difference between women with premenstrual syndrome and control subjects ($p < 0.05$). A decrease in functional performance was observed for premenstrual syndrome subjects in the late luteal phase response relative to that at the early follicular phase testing, when compared with control subjects (Table I). Part II of the Crawford Small Parts Test (with a reliability coefficient of 0.66) was primarily responsible for the significant interaction ($p = 0.015$) between clinical group and menstrual phase (Fig. 1). Initially this test took a mean of 10 minutes, 45 seconds to complete with a range of 8 minutes, 27 seconds to 12 minutes, 45 seconds. The standard error bars in Fig. 1 are given to indicate the level of variability in the scores but are not appropriate to make comparisons between groups because of the repeated-measures design.

Although there were significant learning effects for all the tests, there was no evidence of differences in learning effects between the two groups. The group by phase interaction was nonsignificant in an analysis of variance model that included the scores at the two menstrual phases and the early follicular phase.

The two groups were similar in the mandated age and pregnancy categories but were nonsignificantly different in smoking status and occupation, which could account for the differences in group scores at baseline. The effects of full-time employment compared to part-time employment or homemaker status was controlled for in order to assess the influence of life circumstances on the results. On stratification for working status, the difference between cases and controls persisted in the score changes between the two phases.

The distribution of individual subject dexterity changes for the Crawford Small Parts Dexterity Test—Part II between the early follicular and late luteal phases is illustrated in Fig. 2. A positive value indicates an improvement in score whereas a negative value indicates a worsening in score. Because of learning effects, the score changes tend to be positive. With use of zero as a cut-off value, a sensitivity of 58% and a specificity of 78% were obtained. It should be noted that of the nine subjects who scored lower at the luteal phase, all seven premenstrual syndrome subjects had decreases of >30 units while the two subjects without premenstrual syndrome had decreases of <15 units.

Post hoc power analysis on the other three instruments indicated that the sample size was large enough to detect group differences in mean score changes of one standard error with power of at least 80%. Estimates of reliability for the four instruments ranged from 0.65 to 0.80, which are comparable to those reported in the literature.

Comment

Classic premenstrual syndrome presents as a combination of somatic and psychological symptoms during

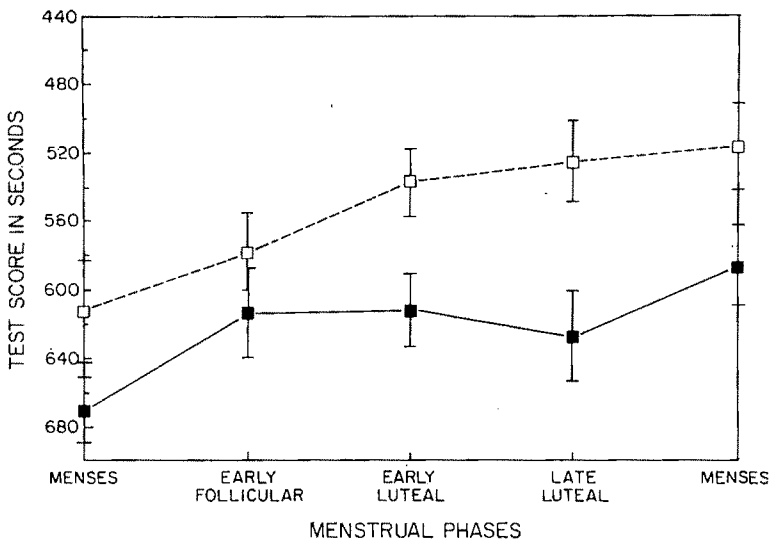

Fig. 1. Group mean profiles of subjects with premenstrual syndrome (■) and controls (□) for the Crawford Small Parts Dexterity Test–Part II. *Bars* indicate standard error of the group means.

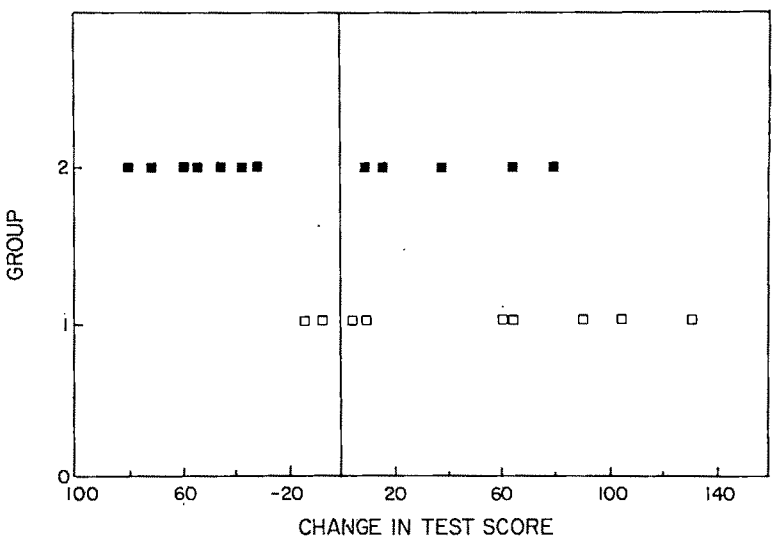

Fig. 2. Distribution of individual score changes in Crawford Small Parts Dexterity Test—Part II between the early follicular and late luteal phases of subjects with premenstrual syndrome (■) and controls (□).

the late luteal phase of the menstrual cycle, with an amelioration of symptoms during menses. In the present study women with premenstrual syndrome did not demonstrate the learning effect in performance on the Crawford Small Parts Dexterity Test–Part II found in the control subjects between the early follicular and the late luteal phase of the cycle. In fact, their performance decreased between these two phases. This test requires manual dexterity in the form of bilateral coordination, balance, concentration, control, and perseverance as 36 small screws are turned into a board with a narrow slotted screwdriver.

The other functional tests did not show differences between the groups in mean score changes. The movements involved in the Minnesota Rate of Manipulation Test require more gross motor performance than fine motor performance. Similarly, the three subtests of the MacQuarrie test assessing mechanical ability do not require bilateral coordination or fine balance and control as does the Crawford Small Parts Dexterity Test—Part II. In addition, since the MacQuarrie tests are shorter in duration, they are less likely to produce fatigue or frustration or to require the same degree of perseverance. The other subtests of the MacQuarrie test along with the Revised Minnesota Paper Form Board primarily test spatial relationships that, based on the present results, do not appear to be disrupted by the menstrual cycle fluctuation.

Zimmerman and Parlee,[14] with use of normal subjects, tested arm-hand steadiness, reaction time, galvanic skin response, time estimation, and digit-symbol substitution, observing that only the arm-hand steadiness test showed statistically significant fluctuations over the phases of a menstrual cycle. These normal subjects showed decreased steadiness during the premenstrual phase when compared with the early luteal phase.

Functional ability over the menstrual cycle has been tested in normal women and generally only in a stimulus-response situation.[4, 5, 15, 16] For the most part these studies do not demonstrate a relationship between performance and menstrual phase.[4, 5, 15, 16] It may be argued that one might expect subjects to display higher functional abilities in a stimulus-response test than one would find in a self-motivating response situation. For example, in the Crawford Small Parts Dexterity Test—Part II, the subject must rotate small screws into a board; since there are no signals for each movement, the subject must motivate herself to perform the task. In a stimulus-response test the subject is prodded to perform by the stimulus so there would be increased performance because of reflex action. A self-motivating type of test, such as the Crawford Small Parts Dexterity Test, may represent a more realistic facsimile of daily functional abilities.

This study has identified a test that is sensitive to decreased bilateral fine motor function in women with premenstrual syndrome during the late luteal phase of the cycle, while showing no such phase effect in normal women. Only in this one bilateral fine motor area did women with premenstrual syndrome demonstrate less functional ability than normal women. Because of the limited number of subjects in this pilot study it was not possible to explore fully whether there are subgroups of the subjects with premenstrual syndrome who are differentially affected. The Crawford Small Parts Dexterity Test—Part II is an objective measure that is potentially valuable in therapeutic trials involving patients with premenstrual syndrome.

Endocrine changes after laparoscopic ovarian cautery in polycystic ovarian syndrome

Ellen Greenblatt, M.D., and Robert F. Casper, M.D.
London, Ontario, Canada

Recently, laparoscopic ovarian cautery has been described as a method of ovulation induction in women with polycystic ovarian disease. In an attempt to determine the mechanism of action, serum levels of androstenedione, testosterone, luteinizing hormone, follicle-stimulating hormone, and estradiol were determined before and after the laparoscopic ovarian cautery in six women with polycystic ovarian disease who had failed to ovulate with clomiphene citrate and human chorionic gonadotropin. Six regularly cycling women undergoing laparoscopy for investigation of infertility or tubal ligation served as controls. In patients with polycystic ovarian disease but not in controls, serum androstenedione, testosterone, estradiol, and luteinizing hormone significantly decreased to nadir levels on postoperative days 3 and 4. In contrast follicle-stimulating hormone levels rose after operation. These results resemble those reported after ovarian wedge resection. Of the six treated women, five ovulated postoperatively and four conceived. Laparoscopic ovarian cautery appears to be a promising alternative treatment for patients with polycystic ovarian disease in whom initial medical management fails. (Am J Obstet Gynecol 1987;156:279-85.)

Key words: Polycystic ovary, laparoscopy, ovarian cautery

Patients with chronic anovulation because of polycystic ovarian disease generally respond to clomiphene citrate administration for induction of ovulation. However, even with the use of increasing doses of clomiphene with or without the addition of human chorionic gonadotropin, 10% to 15% of women remain anovulatory.[1] For these patients, ovulation induction can be difficult, requiring parenteral treatment with human menopausal gonadotropin–human chorionic gonadotropin or pure follicle-stimulating hormone, both of which are costly and require careful hormonal and ultrasound monitoring to prevent a significant incidence of ovarian hyperstimulation.

Alternatively, surgical treatment by ovarian wedge resection, although successful in inducing ovulatory cycles,[2] has largely been abandoned because of the need for laparotomy and the potential for development of pelvic adhesions.[3] Although not thoroughly investigated, recent work suggests that application of microsurgical techniques for ovarian wedge resection may again render this treatment acceptable.[4] The mechanism by which ovarian wedge resection can induce ovulation is unclear; however, investigations of hormonal changes after operation have demonstrated dramatic decreases in serum androgen levels together with equivocal changes in estradiol and luteinizing hormone levels.[5, 6] Recently a less extensive surgical technique involving laparoscopic ovarian cautery has been described for the treatment of anovulation in patients with polycystic ovarian disease.[7] Clinical results appear promising with a high rate of successful ovulation and conception occurring without the need for intensive patient monitoring.

The present study was proposed to evaluate the clinical and hormonal response to laparoscopic ovarian cautery in a selected group of women with polycystic ovarian disease who consistently failed to ovulate with clomiphene citrate and human chorionic gonadotropin. In particular, we examined serum levels of testosterone, androstenedione, estradiol, follicle-stimulating hormone, and luteinizing hormone before and after ovarian cautery to determine if changes similar to those after ovarian wedge resection occurred.

Material and methods

Six women between the ages of 23 and 36 with clinical and biochemical findings consistent with polycystic ovarian syndrome were studied. Criteria for inclusion were the following: infertility secondary to anovulation as indicated by amenorrhea, elevated serum luteinizing hormone levels and normal to low serum follicle-stimulating hormone levels relative to follicular phase values in normal women, clinical evidence of androgen excess (acne, hirsutism), and slightly elevated androgen levels (androstenedione and testosterone). All patients

had failed to ovulate after increasing doses of clomiphene citrate up to a maximum of 150 mg per day with the addition of human chorionic gonadotropin (5000 IU) on day 16 for at least three cycles. The clinical characteristics of these women are shown in Table I. All were being considered for treatment with human menopausal gonadotropin. This study was approved by the University of Western Ontario health sciences committee on human research and informed consent was obtained.

Laparoscopic ovarian cautery was performed with the use of a three-puncture technique. The laparoscope was introduced through a subumbilical incision and a grasping forceps was introduced suprapubically to stabilize the ovary by grasping the ovarian ligament. After assessment of the pelvic structures and tubal patency, laparoscopic scissors connected to a unipolar electrocautery unit were inserted through a third puncture site in the lower abdomen. Eight to ten cautery points 3 to 4 mm in diameter were created in each ovary (Fig. 1) with a current of 4 mA applied through the laparoscopic scissors. Cautery was continued until penetration of the ovarian capsule and cortex was achieved.

The women were studied before and after operation to assess serum levels of the following hormones: luteinizing hormone, follicle-stimulating hormone, estradiol, androstenedione, testosterone, and progesterone. Blood samples were drawn before operation, daily after operation for 2 weeks, and then every 2 days for a total of 4 weeks or until the first menses. All patients were evaluated clinically for up to 18 months.

Six regularly cycling control subjects aged 21 to 33 were selected from women undergoing either diagnostic laparoscopy or laparoscopic tubal ligation for study of the effects of anesthesia and laparoscopy on the serum levels of the above hormones. Two patients were in the early follicular phase and four were in the luteal phase. One preoperative and seven daily postoperative blood samples were obtained.

Blood samples were allowed to clot at room temperature and the serum was separated and frozen at −20° C until assayed. All samples from each patient were run in the same assay. Serum levels of 17β-estradiol and progesterone were determined by previously described radioimmunoassay techniques.[8,9] Luteinizing hormone and follicle-stimulating hormone (Amer-

sham, Oakville, Ontario, Canada; double-antibody iodine 175 radioimmunoassay) and androstenedione and testosterone (Diagnostic Products Corp, Los Angeles, California; solid-phase iodine 125 radioimmunoassay) were measured with the use of commercially prepared kits. Student's *t* test and analysis of variance were used to analyze the data.

Results

There were no complications from the laparoscopic ovarian cautery and all patients were discharged home within 3 hours. Five of the six patients ovulated and menses occurred between 24 and 33 days after operation. Four continued to have regular menses and all of these women became pregnant. One patient ovulated only once after operation and then became amenorrheic but responded to clomiphene citrate, 50 mg, and is ovulating regularly on this dosage. At the time of laparoscopy, this patient had unilateral tubal occlusion and minimal pelvic adhesions on the same side. One patient did not respond and was treated with human menopausal gonadotropin.

Serum concentrations of androstenedione and testosterone before operation and in the first 10 days after operation in the patients with polycystic ovarian disease are shown in Fig. 2. Before operation, the mean (±SEM) serum androstenedione level was 4.77 ± 0.69 ng/ml and that of testosterone was 1.16 ± 0.15 ng/ml. A rapid and significant ($p < 0.01$) decrease in the levels of both hormones occurred after operation, with nadir values of 1.95 ± 0.4 and 0.57 ± 0.1 ng/ml reached on days 4 and 3, respectively. Serum concentrations of luteinizing hormone, follicle-stimulating hormone, and estradiol are shown in Fig. 3. After ovarian cautery, a fall in the serum luteinizing hormone level from 37.6 ± 3.2 mIU/ml before operation to 27.7 ± 2.5 mIU/ml ($p < 0.05$) on day 3 was seen and was followed by a preovulatory surge in five of the six patients. In contrast, the follicle-stimulating hormone levels were seen to rise from a preoperative value of 5.27 ± 0.37 mIU/ml to a peak on postoperative day 2 ($p < 0.01$) of 7.43 ± 0.83 mIU/ml before a return to preoperative values by day 10. Preoperative estradiol levels in the patients with polycystic ovarian disease were 90.2 ± 5 pg/ml; values fell to a nadir of 50.7 ± 6.1 pg/ml ($p < 0.01$) on the fourth day after ovarian cautery. In contrast, control subjects had significantly ($p < 0.01$) lower preoperative androstenedione and testosterone levels (1.6 ± 0.20 and 0.48 ± 0.08 ng/ml, respectively), and these did not change after operation (Fig. 4).

Individual hormone responses in a single patient during her first ovulatory cycle demonstrates clearly the temporal sequence of events after laparoscopic ovarian cautery (Fig. 5). The rapid fall in androgen levels after operation is dramatic and precedes changes in the other hormones. In the single patient who did not respond to ovarian cautery, declines in the concentrations of serum androstenedione, testosterone, and estradiol were similar to those in the women who ovulated after the procedure, but no fall in the serum luteinizing hormone level was observed after operation and the postoperative rise in follicle-stimulating hormone was slower and less marked. No preovulatory peak of serum estradiol or luteinizing hormone occurred.

Comment

Treatment of infertility in polycystic ovarian disease is aimed at reversing chronic anovulation. This group of patients is one of the most sensitive to ovulation

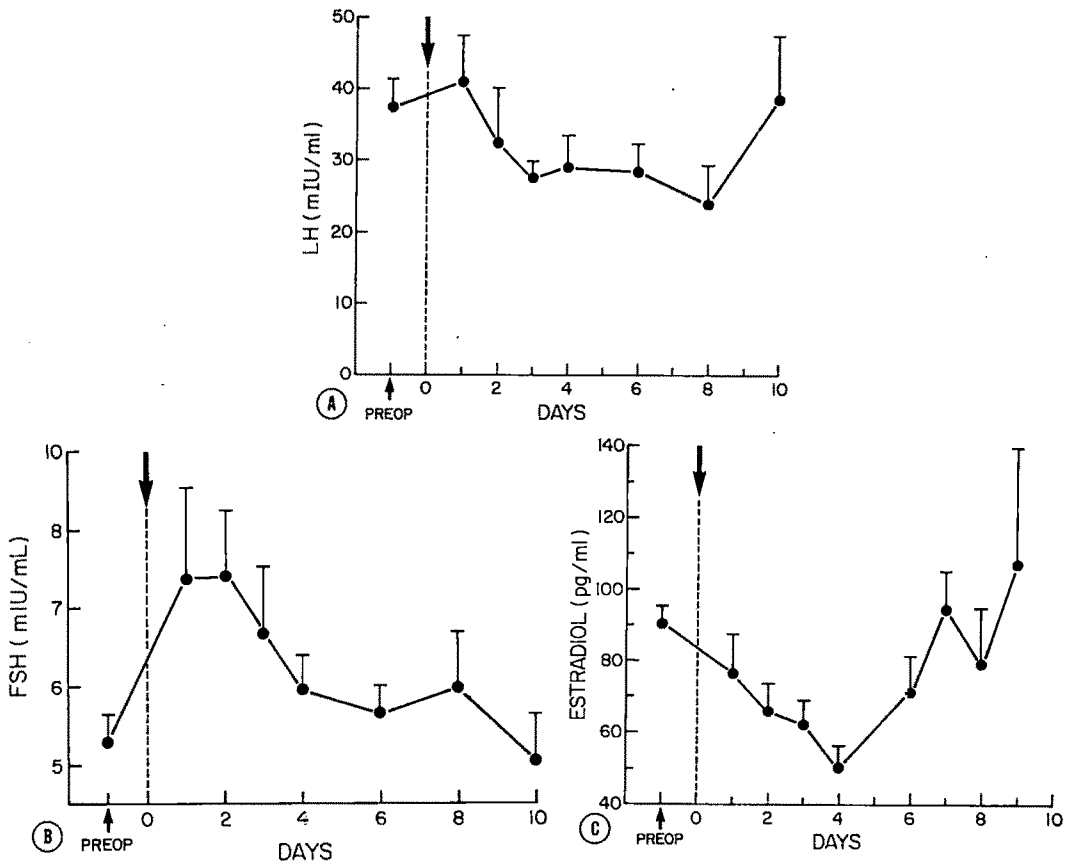

Fig. 3. Preoperative and postoperative gonadotropin and estradiol concentrations in the six patients with polycystic ovarian disease undergoing ovarian cautery. *Arrow* indicates day of operation. *A*, Mean ± SEM serum luteinizing hormone concentrations before operation and 10 days after operation. *B*, Mean ± SEM serum follicle-stimulating hormone concentrations before operation and 10 days after operation. *C*, Mean ± SEM serum estradiol concentrations before operation and 10 days after operation.

induction with clomiphene citrate with response rates of 80% to 90%. For clomiphene citrate failures, the next line of treatment is generally human menopausal gonadotropin and human chorionic gonadotropin with successful induction of ovulation in 75% to 95% of cases.[1] However, human menopausal gonadotropin–human chorionic gonadotropin therapy is costly and demands extensive monitoring to prevent the high incidence of hyperstimulation and multiple births in this group of women.

An alternative means of ovulation induction involves ovarian wedge resection, which was popular at the time that the syndrome was described in 1935.[10] Reports of the incidence of successful ovulation after ovarian wedge resection varies quite widely in the literature with a range of 6% to 95% and a mean of 80%.[2] However, ovarian wedge resection may not be a permanent cure for polycystic ovarian disease,[3] and this treatment has fallen into disfavor because of the significant incidence of postoperative peritubal and periovarian adhesions, which has not been adequately reevaluated in light of more recent microsurgical techniques. The mechanism by which ovarian wedge resection induces ovulation is not known. Early investigators believed that a mechanical barrier to ovulation was removed by incision of the thickened ovarian capsule.[10] However, it is probable that this explanation is too simplistic and several investigators have studied the hormonal alterations associated with ovarian wedge resection in an attempt to determine the mechanism of action.[5,6] The most consistent finding in these studies is a dramatic fall in serum androgen levels in the first few days after operation. Judd et al.[5] studied eight patients with polycystic ovarian disease undergoing wedge resection and described a dramatic decrease in serum androstenedione and testosterone concentrations occurring in the first 3 days after operation. A less dramatic but significant decrease in estradiol with a nadir on postoperative day 3 was also noted. No consistent postoperative alterations in gonadotropins were observed. These investigators suggested that the decreased androgen levels may have removed an intraovarian block

to follicular maturation or that the hyperemia associated with postoperative inflammation allowed increased delivery of gonadotropins. Katz et al.,[6] in a study of two patients, described a similar decrease in testosterone after operation but also observed a decrease in luteinizing hormone levels such that the elevated preoperative luteinizing hormone: follicle-stimulating hormone ratio was normalized. Katz et al. postulated that the postoperative decrease in estradiol and androgens eliminated a persistent positive feedback effect of these steroids on the pituitary, allowing luteinizing hormone levels to return to normal. The normalization of the follicle-stimulating hormone: luteinizing hormone ratio may then allow follicular maturation to proceed.

The present study was designed to characterize the hormonal effects of laparoscopic ovarian cautery as first described by Gjonnaess.[7] In his report on 62 women with polycystic ovarian disease, evidence of ovulation was demonstrated after ovarian cautery in 92% of patients. Of 35 women desiring pregnancy, 69% became pregnant after cautery alone with a total of 80% conceiving after cautery or cautery with the addition of clomiphene. In a subsequent study, Asbjorn and Gjonnaess[11] measured hormonal alterations after laparoscopic ovarian cautery. These authors measured the same hormones 1 day after operation, weekly for 4 weeks, and then periodically up to 1 year and documented ovulation in 72% of 59 women within 4 weeks of cautery. In contrast to the results of the present study, an immediate rise in luteinizing hormone 1 day after operation was seen and this was followed by a gradual fall to levels significantly below preoperative values by day 4. The follicle-stimulating hormone concentrations in these ptients increased significantly on day 1 after operation. Serum concentrations of androstenedione, testosterone, and dihydrotestosterone fell significantly on postoperative day 1 and by 4 weeks after operation they were still lower than pretreatment values.

In the present study, we have demonstrated a dramatic fall in androgen levels in the early postoperative period that is in keeping with similar changes described after wedge resection. However, in contrast to the procedure of wedge resection in which up to 50% of each ovary is removed, only a small percentage of the ovarian cortex and subcortical tissue is destroyed by ovarian cautery. An even smaller removal of ovarian tissue such as occurs with laparoscopic ovarian biopsy can also occasionally induce ovulation in patients with polycystic ovarian disease.[12]

Erickson et al.[13] have demonstrated that dispersed granulosa cells from women with polycystic ovarian disease, when supplemented with follicle-stimulating hormone, have the ability to aromatize androstenedione to estradiol, similar to that of cells from equal-sized follicles from normal ovaries. There does not therefore seem to be an inherent aromatase defect in the polycystic ovary but rather a relative lack of follicle-stimulating hormone. The hypothalamus and pituitary in patients with polycystic ovarian disease can also respond appropriately to steroid feedback signals.[14] McNatty et al.[15] have demonstrated the marked androgen-producing capacity of stromal tissue in polycystic ovaries, and follicular fluid from polycystic ovaries has been found to contain high concentrations of androgens.[13, 15] Therefore it is possible that local factors such as elevated intraovarian androgen levels may contribute to the inhibition of follicular development[16] as seen in patients with polycystic ovarian disease.

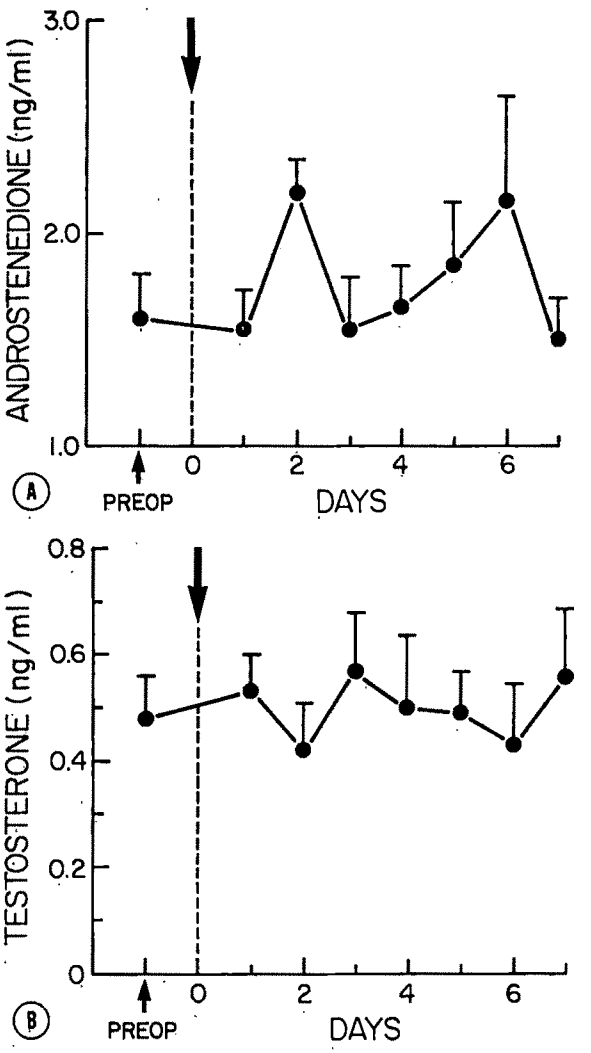

Fig. 4. Preoperative and postoperative serum androgen concentrations in the six control patients undergoing laparoscopy. *Arrow* indicates day of operation. *A*, Mean ± SEM serum androstenedione concentrations before operation and for 1 week after operation. *B*, Mean ± SEM serum testosterone concentrations before operation and for 1 week after operation.

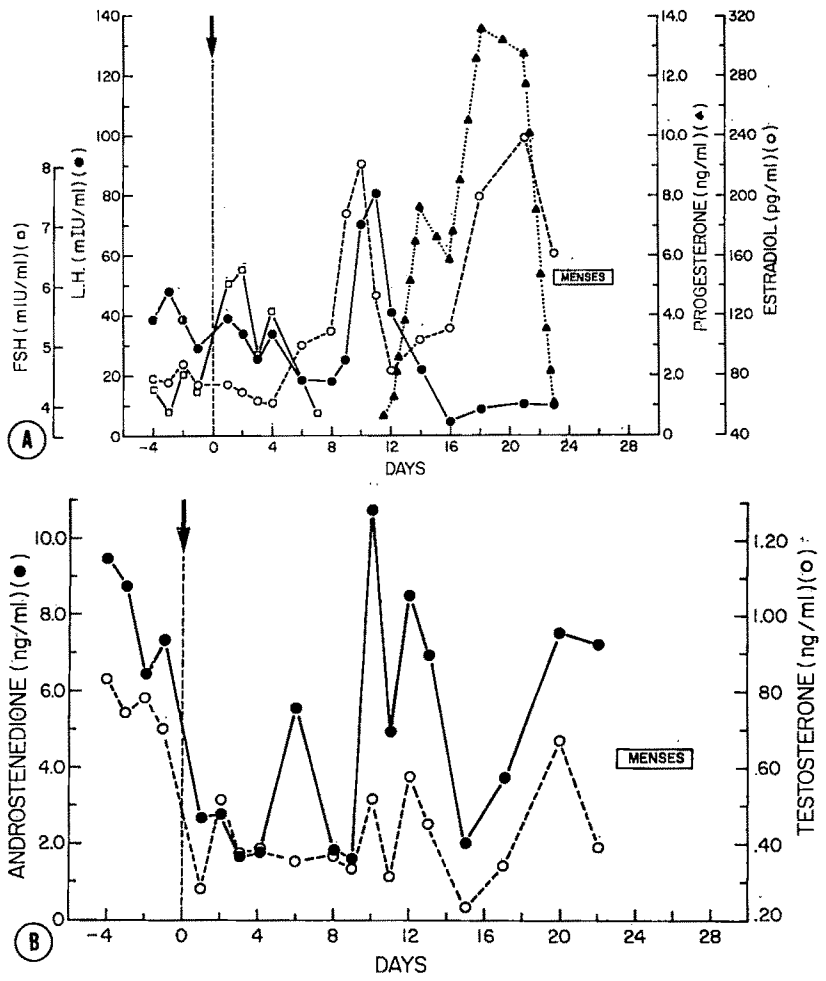

Fig. 5. Example of the pattern of hormonal changes seen in one patient with polycystic ovarian disease treated with laparoscopic ovarian cautery up to the time of the first menses. *A*, Serum concentrations of luteinizing hormone (•), follicle-stimulating hormone (□), estradiol (○), and progesterone (▲) before and after operation. Note preovulatory rise in serum estradiol level and luteinizing hormone surge. *B*, Serum concentration of androstenedione (•), and testosterone (○) before and after operation. Note marked fall in both androgen levels that preceded changes in levels of hormones in *A*.

Trauma to the ovary in various forms (wedge resection, ovarian biopsy, and cautery) may impair local production of androgens. A decrease in androgen levels may result in lowered peripheral conversion of androgen to estrogen and decreased positive feedback on luteinizing hormone production centrally. Negative feedback on follicle-stimulating hormone secretion may also be diminished, allowing follicle-stimulating hormone levels to rise. This may be secondary to a decrease in peripheral estrogens and possibly due to a decrease of inhibin from the cauterized ovary. Lower luteinizing hormone levels might then decrease stromal androgen production and along with increasing follicle-stimulating hormone levels allow follicular development to proceed on to ovulation.

Our data support this hypothesis by demonstrating a drop in peripheral androgen levels preceding the fall in serum estradiol and luteinizing hormone levels. At the same time, follicle-stimulating hormone levels rise, in agreement with Katz et al.,[6] who noted a rise in follicle-stimulating hormone levels after ovarian wedge resection. One may speculate that the fall in local androgen levels and the decrease in the luteinizing hormone: follicle-stimulating hormone ratio would then remove the block to follicular maturation and allow progression to ovulation.

In conclusion, our data demonstrate that laparoscopic ovarian cautery is characterized by dramatic postoperative decreases in androstenedione and testosterone as well as smaller but significant decreases in estradiol and luteinizing hormone. Follicle-stimulating hormone values rise after operation, and this contributes to a decrease in the abnormally elevated luteinizing hormone: follicle-stimulating hormone ratio. These

changes are not a result of anesthesia and laparoscopy alone.

Preliminary clinical results are encouraging. Furthermore, the procedure is relatively simple, adds minimal morbidity to diagnostic laparoscopy, and avoids the complication of hyperstimulation associated with human menopausal gonadotropin–human chorionic gonadotropin therapy. Long-term effects are as yet unknown and the duration of the clinical effects as well as biochemical effects remains to be determined. Larger numbers will have to be treated to ensure the safety of this procedure. Laparoscopic ovarian cautery holds promise for infertile women with polycystic ovarian disease who experience failure of initial medical management.

We wish to thank Wendy Powell and Anne-Marie Powell for excellent technical and nursing assistance.

Human chorionic gonadotropin increase in normal early pregnancy

Salim Daya, M.B., Ch.B.*
Hamilton, Ontario, Canada

Serial determinations of human chorionic gonadotropin have been used in evaluating early pregnancies. This has been based on linear regression of logarithm-transformed hCG levels. However, these levels are changing in a curvilinear fashion as pregnancy advances. Consequently the simple linear model does not provide a good fit to the data. To define more precisely the normal values for hCG increase, serial determinations were performed on serum samples obtained from 29 patients who were carrying normally advancing pregnancies. Gestational age was established with basal body temperature records. Three gestational age periods were identified each with a linear increase in hCG. This was translated into hCG doubling times and percentage increase over time. These tables may be used to determine if an early pregnancy is advancing normally. (Am J Obstet Gynecol 1987;156:286-90.)

Key terms: Pregnancy, normal, early chorionic gonadotropin levels

The development of laboratory assays for the detection of pregnancy began almost 60 years ago with the report of a time-consuming bioassay performed in mice.[1] Since then it was discovered that human chorionic gonadotropin (hCG) was the hormone produced in normal pregnancies and consequently a number of biologic, immunologic, and radioreceptor assays were developed to measure this hormone.[2] One significant development was an antiserum specific for the β-subunit of hCG, thereby allowing very low levels of the hormone to be detected without interference from luteinizing hormone.[3] This high level of sensitivity has enabled hCG to be detected by radioimmunoassay as early as 6 days after conception.[4] With increasing availability of this assay the progress of early pregnancy can be monitored with serial determination of hCG.[5-8]

The majority of the reports in the literature have been based on calculating predicted increases in hCG over time using linear regression of logarithmically transformed hCG levels in the first trimester. With use of this method it has been assumed that the rate of rise of hCG is constant in normal early intrauterine pregnancies. However, hCG levels are constantly changing with the rate of rise decreasing as pregnancy advances until a plateau is reached at approximately 9 to 10 weeks' gestation. Simple linear regression of log hCG does not adequately represent this change. Consequently the predictive value for normal pregnancy with use of doubling times based on this method may lack sensitivity. An attempt to improve this has been made with use of smaller sampling intervals of hCG.[8]

Regression analysis is used to establish whether a relationship exists between two variables. For a particular value of the independent variable, the regression line helps to predict a corresponding best estimate of the dependent variable. By plotting a series of hCG levels for each gestational age, a simple linear regression model can provide a best estimate for hCG level at a particular gestational age. Since hCG levels are increasing in pregnancy in a nonlinear way, this model is not suitable in providing estimates of hCG *increase* over time without the knowledge of gestational age. However, this has been the main focus in the literature.

In this study, normal values for the rate of hCG increase in early pregnancy have been defined more precisely and may improve the sensitivity and usefulness of serial determinations of hCG in the early detection of pathologic pregnancies.

Material and methods

Patients undergoing evaluation and treatment at the Infertility Clinic at Chedoke-McMaster Hospital, Hamilton, Canada, were selected for this study after giving informed consent. Serial hCG determinations were performed on serum samples obtained from 29 such patients who had conceived and were carrying normally advancing intrauterine pregnancies as confirmed by ultrasonography. The mean sampling interval was 3.8 days. All these patients have since delivered healthy

infants at term. Although some patients conceived spontaneously, most required therapeutic intervention in the form of homologous or heterologous insemination, clomiphine citrate, human menopausal gonadotropin, and/or human chorionic gonadotropin. Gestational age was established in all cases by the nadir on basal body temperature recordings.

Radioimmunoassay. Patient serum was separated from clotted blood samples and stored at −20° C. Quantitative measurements of hCG were performed with use of a GammaDab M [iodine 125] β-subunit of hCG radioimmunoassay kit (Travenol-Genentech Diagnostics, Cambridge, Massachusetts). The procedure is a competitive binding assay that uses a precipitating antiserum reagent generated against the β-subunit of the hCG hormone, ^{125}I-labeled hCG, and a highly purified preparation of hCG reagents as control (CA 2426), standard (CA 22002, 22003, 22004, 22006, and 22007) and calibrator/standard (CA 22005). The control reagent is calibrated at 90 mIU/ml, the standards at 5, 10, 25, 100, and 200 mIU/ml, and the calibrator/standard at 50 mIU/ml. The standards and control reagents are calibrated to the World Health Organization's immunoassay standard, the first international reference preparation 75/537 established in 1975, and labeled in international milliunits per milliliter. The values of the controls, standards, and patient serum can be converted directly from international milliunits per milliliter to international units per liter of standard international units. The calculated sensitivity of the assay is 1 to 5 mIU/ml with <5 mIU/ml being taken as evidence for a nonpregnant state. The intrarun variability determined from the mean of 20 simultaneous assays for three samples was 3.2% (range, 2.9% to 3.6%), and the interrun variability determined from the mean of the average of duplicates for 20 separate runs was 7.4% (range, 6.5% to 9.0%).

Statistics. Simple linear regression was performed

on the hCG levels for each patient. Three gestational age ranges were specified (given in the Results section) and within each one the mean and lower two standard deviations (SD) were calculated for the slope parameters.

Results

Since some of the patients had received hCG injections to induce ovulation, clearance studies were performed to determine how rapidly 10,000 IU of this hormone could be eliminated from the body. Daily blood samples were taken for hCG determinations from three such patients. It was observed that hCG was no longer detectable 12 days after the initial administration of this hormone. Subsequently in such patients, blood samples for hCG were not drawn earlier than 12 days after the last hCG dose.

Fig. 1 represents a scattergram of log hCG plotted against gestational age. It can be seen that as gestational age advances, the hCG level increases until a plateau is reached at approximately 9 weeks' gestation. The relationship appears to be a curvilinear one despite the logarithmic transformation. To determine which regression model would best fit the data, the following were tested: straight line, quadratic, and cubic. From Table I it is apparent that all models demonstrate a significant overall regression. However, when lack of fit for each model is tested, the simple linear model is not appropriate ($F_{42,121} = 2.22$, $p < 0.005$) whereas both the quadratic and cubic models are appropriate ($F_{41,121} = 0.956$, $p > 0.25$, and $F_{40,121} = 0.961$, $p > 0.25$, respectively). The quadratic model provides significantly more predictive power than that provided by the straight line model (partial $F_{1,162} = 176$, $p < 0.001$). Also the higher order cubic model does not improve this predictive power of the quadratic model (partial $F_{1,161} = 0.738$, $p > 0.25$) and is therefore not a suitable model to be used, since it is computationally more tedious. The quadratic regression line is shown in Fig. 1. Fig. 2 shows the residuals plotted against gestational age for the straight line and quadratic models and clearly confirms the superiority of the latter model. These statistical analyses confirm that the rate of rise of hCG is not linear but follows a quadratic curve, that is, it decreases as gestational age increases until a plateau is reached.

In view of this curvilinear relationship, gestational age was divided into three phases (Fig. 1) based on what appeared to be the most appropriate divisions when inspecting the scattergram. Polynomial regression analysis for the best-fitting model was performed for each phase (Table II). In each of these phases, all three models demonstrated an overall regression that was significant and all models did not demonstrate a lack of fit indicating that all were appropriate. However, the higher order models did not improve the predictive power of the straight-line model. These results support the three divisions of gestational age and allow inferences to be made within each phase as hCG now increases in a *linear* fashion with gestational age. With this information, simple linear regression analysis was performed on hCG levels for each patient within each phase. The mean and lower 2 SD were calculated for the slope parameters in each phase (Table III). The mean and lower 2 SD of the doubling times were also calculated for each phase (Table IV) with use of the following formula:

$$\text{Doubling time} = \frac{\log 2}{\text{slope}}$$

Doubling times can be translated into a percentage increase in hCG over time for each phase and thereby provide normal values that may be clinically useful (Table V).

Comment

The application of radioimmunoassay to the detection of hCG has provided a very sensitive and specific test that allows the early detection of pregnancy. As this test is becoming more readily available, it is increasingly being used to determine whether an early pregnancy is advancing normally. This is particularly useful in

Table II. Polynomial regression analysis of early pregnancy data per gestational phase

*Linear regression models**	*F values*		
	Overall regression	*Lack of fit*	*Improved predictive power with use of quadratic vs. straight line*

women who are at high risk for recurrent abortion and ectopic pregnancy and also in women who have symptoms of uterine bleeding and/or lower abdominal pain. In these situations, serial hCG determinations are used as prognostic indicators of the status of the pregnancy. To distinguish between normal and ectopic pregnancies, it has been shown that measuring the rate of hCG increase in serum is a more effective method than use of hCG values alone.[7] Several reports have indicated that the serum hCG levels in patients with ectopic pregnancies are much lower than those seen in normal pregnancies.[6,9-11] However, this approach has significant limitations, since often the hCG levels may not be low but the rate of increase may be suboptimal.[12] It would appear that serial hCG determinations would provide more useful information in such cases.

The literature has focused on simple linear regression of log-transformed hCG levels to evaluate early pregnancies. This has resulted in many normal pregnancies being erroneously classified as advancing suboptimally (Daya S, unpublished observations). For example, the straight-line model for the hCG levels in this paper (before subdivision into phases) had a slope of 0.199. The doubling time corresponding to this is 3.48 days. With use of this model, all of the patients who were sampled in phase 2 (gestational age, 41 to 57 days) would be considered as having abnormal hCG increases, since the mean doubling time in this phase was much longer (4.75 days). Similarly, Kadar et al.[12] produced tables showing lower limits of the percentage increase in hCG between test samples drawn several days apart (for example, for a sampling interval of 2 days the percent increase in hCG equals 66%). With use of these tables, many patients sampled in phase 2 in this study again would be considered as having abnormally advancing pregnancies. These interpretations are based on the assumption that hCG increases in early pregnancy at a constant rate. This study clearly shows that the rate of rise of hCG is not constant but is gradually decreasing with advancing pregnancy. The fact that the quadratic regression model provides a better fit for the data than the simple linear regression model supports this observation.

Many of the reports in the literature have used a cohort of patients to provide several samples in order to determine the rate of rise of hCG. This introduces both intrapatient and interpatient variability. The method used in this paper has attempted to reduce

Table V. Percentage increase in hCG over time*

6	757	410	140	73	17	13.7
7	1127	570	177	90	20.3	16

intrapatient variability by use of the slope of hCG increase in each patient to determine the normal values. This allows a more sensitive method of interpreting hCG increases in the pregnant population without having the bias of intrapatient variability.

Division of the gestational age (from day 20 to 66) into three phases has provided a method of evaluating the progress in early pregnancy without violating the principles of regression analysis. The rate of rise is relatively constant in each of these phases. It is important to note that with use of regression analysis, one cannot ignore the gestational age in predicting the rate of rise of hCG. This is especially important in following the cases of women at high risk for spontaneous abortion and ectopic pregnancy so that important prognostic information can be provided. Similarly it may be especially relevant in infertile women who are known to be at high risk of having pathologic pregnancies and in whom gestational age is often known from basal body temperature graphs. In such patients the normal values presented in this paper would be very useful. To determine the minimum acceptable change in hCG required to classify the pregnancy as one that is advancing normally, receiver operating characteristics curve analysis will have to be performed. With use of this method the rate of change in pathologic pregnancies can be compared with normal pregnancies to determine the best "cut-off" that will be clinically useful as a prognostic indicator.

Prevalence of antibody to *Chlamydia trachomatis* in spontaneous abortion and infertility

P. A. Quinn, Ph.D., M. Petric, Ph.D., M. Barkin, M.D., J. Butany, M.D., C. Derzko, M.D., M. Gysler, M.D., K. I. Lie, M.D., A. B. Shewchuck, M.D., J. Shuber, M.D., E. Ryan, M.D., and M. L. Chipman, M.A.

Toronto, Ontario, Canada

A higher prevalence of *Chlamydia trachomatis* antibody occurred in 57.6% of women with recurrent abortion, but not in their male partners, compared to 33.7% of normal pregnant women ($p < 0.01$) and 44.2% of infertile women (NS). The mean titer for the recurrent abortion group was not significantly elevated, compared to controls. Women with blocked fallopian tubes had the highest prevalence of elevated titers ($p < 0.01$) and the highest mean titer ($p < 0.001$). Despite multiple testing, no women or men were chlamydia culture–positive. The lack of isolation among patients with antibody could be due to cryptic infection at a site not amenable to culture or to inhibition by secretory IgA. There could also be nonspecific stimulation of chlamydial antibody caused by other infections such as mycoplasma. The presence, though at a low level, of antibody in culture-negative patients suggests chlamydia may not be directly associated with recurrent abortion but reflect previous exposure to chlamydia or an altered immune system. (Am J Obstet Gynecol 1987;156:291-6.)

Key words: Chlamydia, antibody, recurrent spontaneous abortion, infertility

A number of studies have demonstrated that *Chlamydia trachomatis* plays a prominent role in disorders of the human reproductive system. These include tubal infertility,[1, 2] ectopic pregnancy,[3] and pelvic inflammatory disease.[4] It is the postinflammatory sequelae of the chlamydial infections that are believed to play the major role in the development of the infertile state in the patients.[4] In men these organisms are associated with urethritis, prostatitis, and epididymitis, of which the latter two conditions could affect fertility.[5] Most of these studies have been carried out by examining the serologic status of the populations investigated.

To date there has been little documentation of the role of chlamydial infection in spontaneous abortions. There is evidence, however, that *C. psittaci* is involved in bovine abortion.[6] In the present study the prevalence of antibody to chlamydia is prospectively examined in a major cohort of patients with recurrent spontaneous abortion and compared to normal fertile and infertile patients.

Material and methods

Patient populations. Serum samples were obtained from patients enrolled in two prospective studies. The first study examined the role of infection in spontaneous pregnancy loss from 1984 to 1986. The second study examined the role of genital mycoplasmas in infertility between 1976 and 1980. Blood samples were collected on entry to the first study from couples with two documented pregnancy losses including 63 women who enrolled already pregnant, 38 women who were not pregnant, and 55 of their male partners. The control group included 63 normal pregnant women participating as controls in the spontaneous abortion study and 38 nonpregnant women participating as controls in the infertility study. To provide a comparison population in which chlamydia antibody may be elevated, serum samples were assayed on entry from patients enrolled in the infertility study. These patients included 95 women with infertility of known etiology; 25 women who were infertile for no known cause, that is, "normal"; and 116 male partners of these infertile women. The male control group consisted of 36 partners of the normal pregnant women enrolled as controls in the infertility study.

The serum fraction of the blood collected from the above subjects by venipuncture was stored at −20° C until assayed for chlamydial antibody.

Chlamydia antibody assay. The immunofluores-

Nonpregnant	32	18	56.2	NS	8	25.0	NS

cence microscopy method was used in all assays.[7] The reagents were purchased as a commercial indirect fluorescent antibody kit (Electro-Nucleonics Inc., Columbia, Maryland). The serum samples were first screened at a dilution of 1:8 in phosphate-buffered saline solution (Oxoid Canada, Ltd., Ottawa, Ontario) for the presence of antibody. Those samples manifesting the presence of antibody were then titrated to determine the individual titer. The highest dilution before extinction was taken as the titer of the chlamydial antibody.

Microbiology. Cultures for chlamydia were performed for all couples with recurrent abortions. Cervical and male urethral swabs were taken for culture from the pregnant and nonpregnant couples on entry to the study. Cultures also were made of the endometrial biopsy specimens of the nonpregnant women at the time of entry. Cultures were made of the same male and female specimens at the first prenatal visit and at 20 weeks of gestation for all pregnant couples. *C. trachomatis* was isolated in Hela 229 cells treated with cycloheximide at 2 μg/ml.[8] The specimens were inoculated under centrifugation and monitored at 48 hours by immunofluorescent staining with use of a monoclonal antibody (Syva Diagnostics, Montreal, Quebec).

Data analysis. Comparisons of the prevalence of antibody titers were made with use of the χ^2 test of Fisher's exact test. Mean titers and standard deviations were calculated on the antibody titer converted to $\log_{10}$. The differences in the mean titers were compared by the *t* test.

Results

Prevalence of chlamydia antibody in women with recurrent abortions. Serum samples from a total of 287 women were analyzed for antibody to chlamydia. These were scored for any detectable antibody at a dilution of ≥1:8 and for elevated antibody at a dilution of ≥1:32 as shown in Table I. The latter dilution was interpreted to reflect an appreciable titer of antibody consistent with a relatively recent or severe infection, whereas lower antibody levels were taken to reflect either a milder or more distant infection. The prevalence of any antibody titer (≥1:8) to chlamydia in the normal control women averaged 33.7%. A similar prevalence was seen overall in infertile women. In contrast, the prevalence of any chlamydial antibody in patients with a history of recurrent spontaneous abortion was significantly higher at 57.6% ($p < 0.01$). When the infertile group was subdivided, women with a known cause of pregnancy loss tended to have a higher prevalence than "normal" infertile women. No significant difference was observed in the prevalence of chlamydial antibody between pregnant and nonpregnant recurrent aborters or controls, as shown in Table II.

When the prevalence of elevated antibody titers (≤1:32) was assessed, the recurrent aborters exhibited a trend toward a higher prevalence than the normal

controls, though this was not significant ($\chi^2 = 3.78$). These studies therefore suggest that there is a correlation between a history of recurrent spontaneous abortion and the presence of detectable antibody to *C. trachomatis*.

Prevalence of chlamydial antibody in male partners. The prevalence of antibody to chlamydia was next examined in the male partners of the women with a history of recurrent abortion. As shown in Table III, the prevalence of detectable antibody or an elevated antibody response was comparable in the three groups of men.

Isolation of chlamydia trachomatis from couples with recurrent abortions. In all patients in the recurrent abortion study, cultures were made extensively for *C. trachomatis*. In 33 pregnant and 32 nonpregnant couples, repeat cultures were performed on both partners on entry to the study and during gestation. Despite this repeated testing, chlamydia was not isolated from these recurrent aborters. Identical culture conditions in the same laboratory resulted in an isolation rate of 10% to 15% from a population of sexually active adolescent women presenting with a history of vaginal discharge.

Correlation of chlamydia antibody to causes of infertility. A number of studies have suggested that chlamydial infections play a role in subsequent infertility. Accordingly, serum samples from the infertility study patients were analyzed in reference to the documented causes of their reproductive failure. The presence of any detectable antibody was observed in six of seven (85.7%) of the cases with blocked fallopian tubes compared with 17 of 38 (44.8%) of normal controls. As demonstrated in Table IV, there was a significantly increased prevalence of elevated antibody to chlamydia

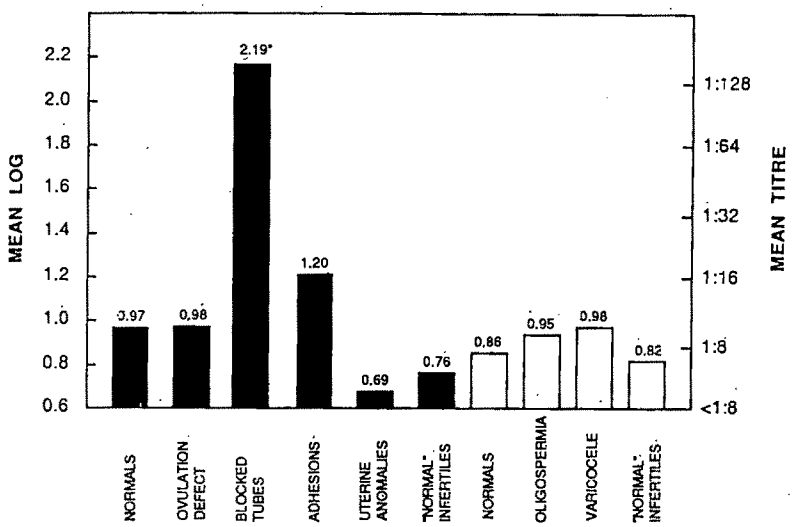

Fig. 1. Mean antibody titers from patients with reproductive failure. *Solid bar,* Women; *open bar,* men. Categories of reproductive failure and controls are indicated. * = $p < 0.01$. Actual mean titers are given over each bar.

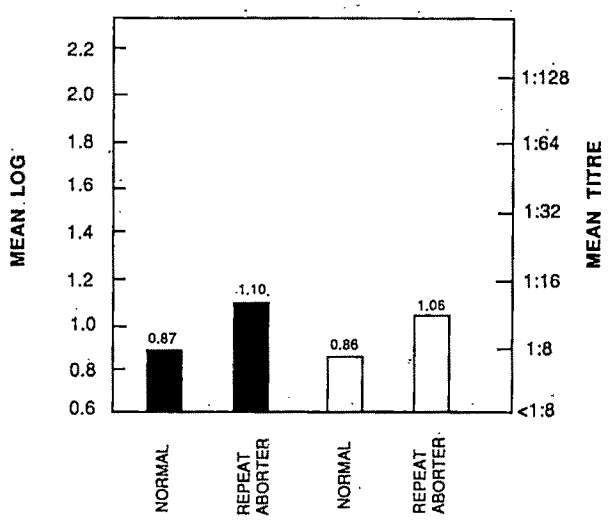

Fig. 2. Mean antibody titers from recurrent abortion patients and normal controls. *Solid bar,* Women; *open bar,* men. Actual mean titers are given over each bar.

in cases with blocked tubes ($p < 0.01$). The second group that exhibited a higher incidence of chlamydial antibody were five women with adhesions, of which three had detectable antibody and two had elevated levels.

Mean antibody titers among couples with reproductive failure and recurrent abortion. To determine whether there was an overall difference in the chlamydial antibody response, the mean titer for each group was compared. The highest mean titer occurred among infertile women, clinically diagnosed as having blocked tubes, as shown in Fig. 1 ($p < 0.01$). Women with adhesions had a slightly higher mean titer. Overall, women and partners with infertility resulting from other defined causes had mean titers comparable to normal controls. When the mean titer of women and partners with a history of recurrent abortion were compared to normal controls, there was no significant difference, as shown in Fig. 2.

Comment

A role for chlamydia infection in recurrent abortion has been proposed but not documented at this time. In our studies of infection in perinatal death, no evidence of chlamydial infection was found in the cases studied.[9] In this study on infection in couples with recurrent spontaneous abortion, patients were examined, by culture and serologic methods, for evidence of chlamydial infection. An increased prevalence of detectable chlamydial antibody was observed in patients with a history of recurrent abortion compared to normal fertile couples. The prevalence of elevated antibody titers was also higher. However, the mean titer was not higher than that of the control group. There was no evidence of an increased prevalence of chlamydial antibody in spouses of recurrent aborters. No difference was observed in the prevalence of chlamydial antibody between pregnant and nonpregnant women. Hence the pregnant state did not itself significantly affect the patients' immune status to chlamydia.

In patients with blocked fallopian tubes, a previously reported sequela of chlamydial infection, both elevated individual titers, and an elevated mean titer, were observed. These latter observations not only confirm the previously reported prevalence of chlamydial antibody in this group[1] but also serve as a positive control on our assay system. The prevalence of low-level chlamydial

antibody of 33.7% in the local normal population is lower than the 71.6% reported elsewhere.[1] This may well be due to the fact that women in our reproductive failure studies are older with a mean age of 28 to 30 years.[9] Evidence of chlamydial infection in these women is less when compared to infection in our adolescents who have a higher rate of isolation of the organism. Further studies are required to determine when women with recurrent abortions actually develop the antibody to chlamydia. In a recent study, residual chlamydial antibody was detected up to 6 years after an episode of pelvic inflammatory disease.[10]

Despite repeated testing, no chlamydia were isolated from this group of couples with recurrent abortion. This suggests that these organisms were either not present at the time of sampling or were present at deeper sites that were not amenable to sampling or their isolation was inhibited by the presence of secretory IgA.[10]

The above results mainly suggest an association of chlamydia antibody and recurrent abortion. There could, however, be other explanations for these antibody responses. A large number of the recurrent aborters are colonized in the genital tract with mycoplasmas, particularly *Ureaplasma urealyticum.* Hence the above two infectious agents may have been acquired simultaneously. The presence of chlamydia antibody could therefore be due to residual antibody from past infection. Since the mean chlamydial antibody titers were not as high in the recurrent aborters as in the patients with blocked tubes, the former patients may have had a more superficial infection. In this study, since no chlamydia were isolated from the recurrent aborters and the mean titer was relatively low, the data suggest that the organisms were not likely to be playing an active role at the time of the study.

Recent evidence strongly suggests that *U. urealyticum* is associated with infection in pregnancy. In women with placentas positive for *U. urealyticum,* there is an association with chorioamnionitis, low birth weight, spontaneous abortion, stillbirth, prematurity, and neonatal death.[9, 11, 12] In cases of perinatal death there is a higher prevalence of the isolation of *U. urealyticum,* an elevated maternal and fetal ureaplasma antibody, and the presence of chorioamnionitis, particularly among cases with no morphologic cause of death.[9, 13]

Since many recurrent abortion patients appear to be infected with *U. urealyticum,* this mycoplasma, like *Mycoplasma pneumoniae,* may nonspecifically alter the patients' immune system.[14] *M. pneumoniae,* the only human mycoplasma infection studied extensively, has been shown to act as a nonspecific polyclonal B cell activator. During episodes of *M. pneumoniae* infection, increases in antibody titers to previous viral infections have been documented and the formation of various autoantibodies described.[14] It is therefore possible that other mycoplasma infections, such as *U. urealyticum,* could nonspecifically stimulate the production of chlamydial antibodies in patients with past chlamydial infections or make them more susceptible to other types of infection.

We have now documented that women with recurrent abortions have elevated antibody titers to *U. urealyticum*[9, 13] and to chlamydia. Recent reports suggest that women with recurrent abortions may have an alteration in their immune system, with the production of antiphospholipid antibodies such as lupus anticoagulant antibody, anti–deoxyribonucleic acid, smooth muscle and cardiolipin antibodies that cross-react in the VDRL antibody test.[15] With *M. pneumoniae* infection, various autoantibodies including cold agglutinins, cold reactive antilymphocyte antibodies, antibodies to brain, lung, smooth muscle, and perhaps most important, to cardiolipin of both IgM and IgG classes have been documented.[14] *M. pneumoniae,*[14] *M. hominis,* and recently *U. urealyticum* have been shown to synthesize phospholipids, and the latter have phospholipases.[16] In *M. pneumoniae,* this phospholipid is distinct from cardiolipin but is reactive with Wassermann-positive sera.[14]

Since the presence of various phospholipid antibodies is being found in recurrent aborters and since ureaplasma infection is associated with intrauterine infection and pregnancy loss in the same population, the two factors may be indirectly associated. It is therefore important that immunologic and infection studies of recurrent abortion patients be coordinated.

In conclusion, elevated antibodies to chlamydia have been detected in a recurrent abortion population. They may not be directly associated with current infection but rather reflect a past infection or alteration of the immune system.

We wish to acknowledge the able technical assistance of S. Mitra and M. Wojtak.

Infertility surgery for pelvic inflammatory disease: Success rates after salpingolysis and salpingostomy

Mark Carey, M.D., and Stan Brown, M.D.
London, Ontario, Canada

Eighty-seven patients with infertility due to pelvic inflammatory disease were retrospectively studied to determine pregnancy rates after infertility surgery. Patients were divided into two groups on the basis of the type of surgical procedure: group 1, lysis of adhesions only (22 patients); group 2, terminal salpingostomy with lysis of adhesions (65 patients). A significantly greater number of patients in group 1 (nine of 22, 41%) than in group 2 (12 of 65, 18%) ($p < 0.05$) achieved intrauterine pregnancy. The incidence of ectopic pregnancy was 23% in group 1 (five of 22) and 9% in group 2 (six of 65) ($p = 0.12$). Almost all pregnancies that were conceived more than 16 months after operation were ectopic gestations. Patients were classified according to severity of disease on the basis of several factors. Although few patients with severe pelvic inflammatory disease conceived after operation, the effect of disease severity on the likelihood of successful operation was not statistically significant. (AM J OBSTET GYNECOL 1987;156:296-300.)

Key words: Pelvic inflammatory disease, infertility surgery, salpingostomy

There are numerous studies in the literature that examine pregnancy rates after tubal reconstructive surgery.[1-5] Many of these studies include patients with a variety of causes of infertility. As well, the accuracy of reported pregnancy rates may be questioned in some studies where patients were not analyzed with respect to the type of surgical procedure. The aim of this study was to examine the success rates of fertility-promoting surgery specifically in patients with pelvic inflammatory disease. Patients were categorized according to the type of surgical procedure, and factors thought to influence the likelihood of a successful operation were studied.

Material and methods

From January 1978 to April 1985 a retrospective review was performed on all patients in the senior author's practice (S. Brown) who underwent tubal microsurgery. Patients were selected for entry into the study if they fulfilled the following requirements: (1) infertility >1 year's duration, (2) no other significant causes of infertility aside from obstructed fallopian tubes or periadnexal adhesions that were secondary to pelvic inflammatory disease, and (3) follow-up of >18 months' duration. Patients with endometriosis or proximal tubal obstruction were excluded from the study. Patients who required salpingostomy were included only if a terminal salpingostomy was performed.

All patients underwent a complete infertility investigation, which included history, physical examination, documentation of ovulation, evaluation of serum prolactin level, laparoscopy, and hysterosalpingography in

Table I. Patient characteristics

Characteristic	*Group 1: Lysis of adhesions (n = 22)*	*Group 2: Salpingostomy (n = 65)*
Age (yr) (mean ± SD)	28 ± 3.7	28 ± 4.2
Primary infertility	8 (36%)	35 (54%)
Secondary infertility	14 (64%)	30 (46%)
Follow-up (mo) (mean ± SD)	42 ± 17	43 ± 17
Lost to follow-up	1 (4.5%)	6 (9%)
Previous infertility surgery	2 (9%)	12 (18%)
Previous ectopic pregnancy	7 (32%)	9 (14%)
Ovulatory dysfunction (No. given clomiphene citrate)	3	3
Mild hyperprolactinemia	1	0

selected cases; all husbands had a normal semen analysis.

The patients were then divided into two groups: group 1 (22 patients) included those patients with periadnexal adhesions and patent fallopian tubes who required lysis of adhesions only. Patients requiring lysis of fimbrial adhesions were included in this group. Group 2 (65 patients) consisted of patients with distal tubal obstruction who required salpingostomy and lysis of adhesions.

All patients were cared for and operated on by the same surgeon. Operation was performed according to conventional microsurgical techniques.[6] Prophylactic antibiotics were used in all patients and treatment was continued for 10 to 14 days after operation. Steroids and antihistamines were not used. One hundred milliliters of 70% dextran was routinely instilled into the pelvis just before the abdomen was closed. Postoperative hydrotubation was not performed.

Detailed operative reports were available on each patient and an analysis of various factors that might have influenced the outcome of operation was performed. The extent of adhesions were classified as follows: mild, fine filmy adhesions covering less than one third of the surface of the tube and/or ovary; moderate, adhesions covering one third or more of the surface of the tube and/or ovary, with tissue planes evident; severe, thick fibrovascular adhesions covering most of the surface of the tube and/or ovary, with destruction of normal tissue planes making dissection very difficult.

Tubal dilatation was classified according to measurement; the categories being normal, ≤2 cm dilatation, or >2 cm dilatation. The condition of the distal tubal mucosa was graded as follows: good, normal mucosa on examination with magnification; fair, patchy areas of normal and abnormal mucosa; poor to absent, no normal mucosa visible or only an isolated area of normal mucosa present. Patients undergoing unilateral salpingostomy with a patent opposite fallopian tube were excluded from the analysis regarding the above factors.

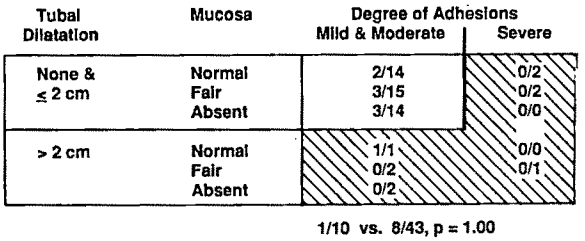

Fig. 1. Factors affecting surgical success classified according to the side of least disease. (Values are number of pregnancies/ number of operations.)

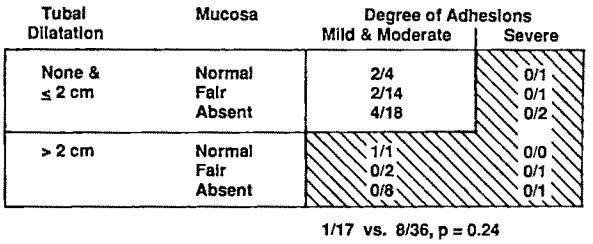

Fig. 2. Factors affecting surgical success classified according to the side of most disease. (Values are number of pregnancies/ number of operations.)

Pregnancies were counted as such only if there was documented evidence of intrauterine or extrauterine pregnancy. This included ultrasound examination in an early intrauterine pregnancy or pathologic examination of the products of conception in cases of spontaneous abortion or ectopic pregnancy. Intrauterine pregnancies were counted only once per patient. Follow-up was maintained for at least 40 months in those patients who did not conceive. Statistical analysis was performed with the use of χ^2 analysis with continuity correction and Fisher's exact test when appropriate. Continuous data were analyzed with the use of Student's t test.

Results

The characteristics of the 87 patients included in the study are shown in Table I. There was no significant difference between groups 1 and 2 with respect to mean ages or the incidence of primary or secondary infertility. When group 1 and group 2 were examined separately, there was no significant difference in age or previous fertility status when those patients who had intrauterine pregnancies were compared with those who did not. Three patients in each group had evidence of ovulatory dysfunction, which was successfully treated with clomiphene. One woman in group 1 had mild hyperprolactinemia, which responded well to bromocriptine.

The overall pregnancy rates and the mean time intervals from operation to pregnancy are presented in Table II. In group 1 (lysis group with lysis of adhe-

sions), nine patients (41%) had a documented intrauterine pregnancy, and five patients (23%) had tubal ectopic gestations. In group 2 (salpingostomy group) 12 patients (18%) achieved intrauterine pregnancy, while six patients (9%) had tubal pregnancies. The differences between intrauterine pregnancy rates in groups 1 and 2 were significant ($p < 0.05$), while the differences in ectopic pregnancy rates were not ($p = 0.12$). The mean time interval from operation to pregnancy was significantly longer in patients with ectopic gestations than in those with intrauterine pregnancies ($p < 0.05$).

Group 1 was further subdivided according to the severity of adhesions (Table III). There was a trend toward a higher chance of intrauterine pregnancy in the group who had lysis of mild adhesions. This trend, however, was not statistically significant.

Table IV summarizes the surgical procedures in group 2. Forty-three patients underwent bilateral salpingostomy and eight patients (19%) had subsequent intrauterine pregnancies. It should be noted that all patients in group 2 had some form of periadnexal adhesiolysis. Twenty-five percent of the 12 patients who underwent unilateral salpingostomy with the opposite

tube patent achieved intrauterine pregnancy, while only one of 10 patients successfully conceived in the group that had a unilateral salpingostomy with the opposite tube absent. None of the differences in the pregnancy rates between the three groups illustrated in Table IV were statistically significant.

Figs. 1 and 2 summarize the pregnancy rates in group 2 (65 patients) according to the various factors analyzed. Patients who had a unilateral salpingostomy and patent opposite fallopian tubes (12 patients) were excluded from this analysis. In many cases it was apparent that the degree of tubal disease differed between the right and left sides in the patients who underwent bilateral salpingostomy. For this reason, the analysis of the various factors that might influence pregnancy rates was done in two ways. In Fig. 1 patients were categorized according to the side of least disease, whereas in Fig. 2 patients were categorized according to the side with the most disease.

In both Figs. 1 and 2 patients with severe adhesions or tubal dilatation >2 cm were unlikely to achieve intrauterine pregnancy after operation. The condition of the tubal mucosa did not seem to alter pregnancy outcome but the numbers are too small for meaningful statistical analysis. Most pregnancies occurred in the mild to moderate dilatation-adhesion categories, and therefore these categories were grouped together in Figs. 1 and 2 for simplification. Using either classification system, we were unable to prove that there was a significant difference in the proportion of pregnancies between the severe dilatation-adhesion group and the mild to moderate dilatation-adhesion group, as illustrated by comparison of the proportion of pregnancies in the *shaded* versus the *unshaded* areas in Figs. 1 and 2.

Pregnancy outcome was also examined in patients who had previous infertility surgery (lysis of adhesions with or without salpingostomy) and in those who required a previous operation for an ectopic pregnancy. Groups 1 and 2 were combined because of the small number of patients (Table V). The intrauterine pregnancy rates and ectopic pregnancy rates are outlined in Table V.

Comment

Jansen[7] has previously reported that patients with patent fallopian tubes have a significantly better chance of conceiving after fertility surgery than patients with obstructed tubes. In his study, 54% of patients who underwent salpingolysis conceived whereas only 19% of patients with bilateral tubal obstruction became pregnant after operation. This study reports very similar figures, with intrauterine pregnancy rates of 41% in the group with lysis of adhesions (group 1) and 18% in the group requiring salpingostomy (group 2). Jansen was also able to demonstrate a significant difference in pregnancy rates between patients with unilateral versus those with bilateral tubal obstruction (43% versus 19%). In this study the improved pregnancy rates found in the patients with unilateral tubal obstruction (25%) were not significantly different from those of patients with bilateral obstruction (19%).

Ectopic pregnancy was a significant cause of morbidity in this study. There was a 23% incidence of ectopic pregnancy in group 1 and a 9% incidence in group 2. Patients with previous infertility surgery or ectopic pregnancy, although few in number, were also at risk for ectopic gestations. An interesting finding was the lengthened mean time interval from operation to pregnancy in patients with ectopic pregnancies. There was only one intrauterine pregnancy conceived more than 16 months from the time of operation. With a follow-up period of at least 40 months for all patients who did not conceive, it is reasonable to conclude that there is a high risk of ectopic pregnancy in patients who conceive more than 16 months from the time of operation.

The outcome of those patients undergoing bilateral salpingostomy was disappointing. Caspi et al.[2] have reported similar results, with intrauterine pregnancy rates of 20% and ectopic pregnancy rates of 9% in patients after operation for bilateral tubal occlusion. Gomel[8] has reported term pregnancy rates as high as 30% in 89 patients requiring salpingostomy with a 9% ectopic gestation rate.

In patients requiring salpingostomy we were not able to demonstrate a significant effect of the severity of disease on pregnancy outcome. Previous studies by Verhoeven et al.[5] and Rock et al.[9] were able to identify a group of patients with "mild disease" whose chances for pregnancy were significantly better than those of patients with more severe disease. Pregnancy rates for "mild disease" varied from 30% to 40% in Verhoeven's study and were approximately 80% in Rock's study. Pregnancy rates dropped dramatically to ≤10% in patients with severe disease. We were unable to identify such a favorable group of patients. This difference may be related to inherent differences in the patient population and smaller sample sizes, or it may be the result of the effect of our classification system. The effect of classifying patients according to the side of least and most disease, as shown in Figs. 1 and 2, illustrates the subjective nature of classification shemes. Differences in classifying patients may result in marked differences in outcome, rendering comparisons between studies difficult. In the present study, classifying patients according to severity of disease on the basis of the side most diseased best identified those patients not likely to benefit from operation. It appears that there may be a group of patients with severe pelvic inflammatory disease who do not have a reason-

able chance for a successful operation. However, a larger sample size would be needed to prove this statistically.

The management of patients with infertility secondary to pelvic inflammatory disease should be individualized. Patients with patent fallopian tubes are better candidates for operation than those with obstructed tubes. In many patients in vitro fertilization may be a reasonable alternative to operation; its use depends on the in vitro fertilization program availability, the cost, and the patients' needs.

Temporal variation in rates of cesarean section for dystocia: Does "convenience" play a role?

William Fraser, M.D., Robert H. Usher, M.D., Frances H. McLean, B.Sc.N., Carol Bossenberry, B.N., Mary Ellen Thomson, Ph.D., Michael S. Kramer, M.D., L. Paul Smith, M.D., and Hugh Power, M.D.

Montreal, Quebec, Canada

The purpose of this study is to test the hypothesis that convenience for the physician plays a role in the rate of cesarean section performed because of dystocia. Three time periods were defined (night, 12 midnight to 7:59 AM; day, 8 AM to 5:59 PM; evening, 6 PM to 11:59 PM) based on the work commitments and daily routines of the obstetrician. Rates of cesarean section for dystocia were determined for each of the three time periods. An evening peak in the cesarean section rate is partially but not entirely explained by an evening increase in the proportion of patients in prolonged labor. When patients were stratified according to labor duration (<12, 12 to 15, and >16 hours), a persistent evening excess in the rate of cesarean section for dystocia was observed for patients whose labor duration was <16 hours. Although this is interpreted as being consistent with the hypothesis of physician convenience, the magnitude of this effect on the overall rate of cesarean section for dystocia is small. (AM J OBSTET GYNECOL 1987; 156:300-4.)

Key words: Cesarean section, dystocia, temporal variation, obstetric convenience

The rapid rise in the rate of cesarean section has come under increasing scrutiny in recent years.[1,2] Performance of cesarean section because of dystocia is of particular concern. Dystocia is the most common indication for primary cesarean section and provides the greatest room for diagnostic discretion.

To what degree does convenience for the physician influence the rate of cesarean section for dystocia? We hypothesized that if this factor is important there should be a regular temporal variation in cesarean section rates in accord with the relative availability of the obstetrician to the delivery room. Cesarean sections for dystocia would be expected to occur less frequently during the nighttime hours of sleep and the daytime period of scheduled office hours and of surgical and teaching commitments. Evening hours would be expected to have the highest incidence, both because of

fewer conflicting obligations and in order to terminate desultory labors before the normal hours of sleep. Lower rates might also be expected on weekends when one obstetrician is "on call" for his group and does not have conflicting work obligations.

The present study was designed to test the hypothesis that physician convenience plays a role in the decision to perform a cesarean section for dystocia. The practice setting studied is similar to most obstetric situations in private practice. The role of variables other than physician convenience in producing differential cesarean section rates for dystocia by time of day was also explored. An unexpected confounding factor, temporal variation in the proportion of patients in prolonged labor, was discovered. This required careful control in order to attempt to isolate the contribution of physician convenience.

Method

The study was carried out at the Royal Victoria Hospital, a tertiary-care teaching hospital of McGill University in which approximately 3500 women are delivered each year. Deliveries are performed by obstetrician-gynecologists, most of whom perform between 100 and 200 deliveries each year. More than 95% of women who are delivered receive their antenatal care in the private offices of attending staff members. In general, daytime coverage is provided by each obstetrician for his or her own patients, while night and weekend coverage is organized in groups with one physician covering for three to six group members. The obstetrician on call usually comes to the hospital from outside for each delivery. Though deliveries are usually also attended by the house staff, an attending staff obstetrician is almost always present at the time of delivery. Remuneration for all deliveries is from the provincially funded health insurance program. There is no differential tariff for procedures by time of day, and there is little difference between the fee for cesarean section and vaginal delivery.

The study population was selected to focus on the category of patients principally at risk for dystocia: nulliparous women with singleton fetuses in cephalic presentation at term (gestational age >37 weeks). Induced labors were excluded, since inductions are generally initiated early in the day and are followed by a higher incidence of cesarean section for dystocia than are spontaneous labors.[3]

All patients presenting in spontaneous labor on admission to the hospital between January 1978 and April 1984 and meeting the above criteria were included in the study (n = 4232). Data were obtained from the computerized McGill Obstetric and Neonatal Data Base.[4,5] The indication for cesarean section was the one recorded by the obstetric team at the time of delivery. For the purposes of the present study, cesarean sections performed either for failure to progress or for cephalopelvic disproportion were included under the category of dystocia. When fetal distress was recorded as an associated indication along with dystocia, such cesarean sections were considered to have been performed for dystocia.

Only those cesarean sections performed during the first stage of labor were included. Second-stage dystocia has more precisely defined limits and involves a different range of management options than those in the first stage.

Labor onset was defined as time of admission to hospital in established labor, which is an objective and verifiable point of reference for women in labor of spontaneous origin. Women admitted, with or without spontaneous rupture of membranes, whose labor began after admission to hospital were excluded.

Diurnal variation in the incidence of cesarean section for dystocia was analyzed in three time periods chosen a priori: day (8 AM to 5:59 PM), evening (6 PM to 11:59 PM), and night (12 midnight to 7:59 AM).

The rate of cesarean section for dystocia by time of day was expressed in each of two ways: (1) as a pro-

Table III. Hourly risk of cesarean section for dystocia

	Patient-hours of labor	*Cesarean section*

*Mean number of laboring patients per hour for the time period, and mean proportion of laboring patients per hour who were in prolonged labor.

portion of the total deliveries during the time period and (2) as an hourly rate per 100 patient-hours of labor. This latter rate (number of cesarean sections for dystocia per number of patients in labor duing each hour of the day) was considered the more appropriate, because the patients at risk of requiring a cesarean section because of dystocia are those in labor rather than those delivering at a particular hour. Since cesarean sections for dystocia occur much more frequently in patients with prolonged labor and since there was a diurnal variation in incidence of prolonged labor, the rate of cesarean sections for dystocia was also expressed per number of patient-hours of labor of "normal" duration (<12 hours), "longer than average" (12 to 15 hours), and "very prolonged" (>16 hours) at each time of day. The rates of cesarean section for dystocia on weekdays (Mondays to Fridays) and weekends (Saturdays and Sundays) were also determined separately. Statistical calculations were performed by the χ^2 test for proportions and by one-way analysis of variance for differences in means.

Results

Table I expresses cesarean section deliveries as a percent of total deliveries by day of week. Although there is a trend toward fewer cesarean sections for dystocia on weekends than on weekdays (3.78% versus 4.76%), this trend does not achieve statistical significance.

On weekdays the rate of cesarean deliveries varied markedly by time of day, with a significantly higher rate occurring in the evening ($p < 0.01$). A similar trend was seen on weekends, but this did not achieve statistical significance (Table II).

When expressed as 100 patient-hours of labor, cesarean section rates for the laboring population were more than twice as high in the evening as during the day or night ($p < 0.001$) (Table III). For these and subsequent calculations, weekday and weekend data were combined.

Table IV shows the proportion of patients in prolonged labor by time of day. It indicates that during the evening the proportion of patients who were in prolonged labor was twice as great as during the night. Thus the observed evening peak in cesarean sections may be at least partially explained by an evening peak in prolonged labors.

It remained to be determined whether, for patients of similar labor duration, there was temporal variation in the rate of cesarean section for dystocia. To control for variation by time of day in incidence of prolonged labor, laboring patients were stratified in the manner previously described: those with normal labor duration (<12 hours), longer-than-average labor (12 to 15 hours), and very prolonged labor (>16 hours). Table V expresses cesarean section rates per 100 patient hours of labor for the three groups. For patients in very prolonged labor the risk of cesarean section for dystocia did not vary by time of day. For patients with shorter labors, however, the risk of cesarean section varied significantly by time of day, with peak rates occurring in the evening.

Table VI shows mean cervical dilatation at the time of cesarean section and mean labor duration for patients delivered by cesarean section by time of day. Neither cervical dilatation nor duration of labor before cesarean section was found to vary significantly among the three time periods.

Table VII explores other potentially confounding variables that could influence the frequency of cesarean section for dystocia: maternal age, maternal height, maternal weight, and fetal weight. None was found to differ among populations delivered at different times of the day.

Comment

The present study setting is typical of private obstetric practice in North America, in which hospital deliveries are performed by obstetrician-gynecologists whose offices are usually located outside the hospital. From the standpoint of the obstetrician practicing in this setting, there are more and less convenient times to perform cesarean sections for dystocia.

The study began with the stated assumption that if temporal variation in rates of cesarean section for dystocia were demonstrable, this variation might reasonably be attributed to physician convenience. In the course of the study, however, it became evident that this assumption required qualification. The proportion of patients in prolonged labor, which is closely linked

to rates of cesarean section for dystocia, varied considerably by time of day. This variation resulted from an unexpected diurnal variation in time of onset of labor. Admission of patients in spontaneous labor occurred more than twice as frequently during the night hours as during the day (Fraser W, Usher R. Diurnal variation in onset of labour. Submitted for publication). This resulted in a sinusoidal admission curve similar to that described by Shettles[6] for the time of labor onset. The evening period, falling 12 to 18 hours after the nighttime peak of admissions, had the highest proportion of patients in prolonged labor.

It then became necessary to modify the question in the following manner: Do patients who have been in labor for similar lengths of time differ in their risk of cesarean section for dystocia according to the time of day? Patients were stratified by number of hours in labor in a manner which, although not providing complete standardization, should have eliminated most of the difference in mean labor duration between subgroups. After controlling in this manner for the uneven distribution of women in prolonged labor, there remained a persistent excess in cesarean sections for dystocia during the evening hours, except for patients in very prolonged labor for whom the rate of cesarean section was similar at all times of day.

If the decision to perform cesarean section for dystocia was being taken at a lower threshold during the evening, shorter labors and lesser cervical dilatations at the time of cesarean section might be expected. Such differences were not observed. How does one account for this negative finding? It seems that cesarean sections for dystocia were performed on the same category of laboring patient (cervix dilated approximately 5 cm and labor duration approximately 13 hours) regardless of time of day. However, more of these patients were selected for cesarean section during the evening hours.

Are there factors other than physician convenience that could vary by time of day to influence cesarean section rates? Patient tolerance to prolonged labor may be decreased in the evening as a result of fatigue, and this could influence decision making. Availability of nursing staff, house staff, anesthesia staff, and operating room time vary by time of day in some hospitals. In the present study such personnel were in, or immediately available to, the labour and delivery suite around the clock, and a special operating room for

primary cesarean sections was situated within the labour and delivery area.

There have been previous attempts to examine the question of temporal variation in cesarean section rates. Phillips et al.[7] examined cesarean section rates by day of week. His findings in a comparison of weekend and weekday rates were consistent with our own. However, inductions were not excluded from his study population. Evans et al.[8] classified cesarean sections into "acute" and "nonacute" and found fewer nonacute cesarean sections were performed at night than at other times of day. Temporal variation in the proportion of patients in prolonged labor was not considered.

In the present study, temporal variation in rates of cesarean section for patients of similar labour duration, though demonstrable, had a relatively small impact on the overall rate of cesarean section for dystocia. Although this evening peak is consistent with the hypothesis of physician convenience, elimination of this "excess" number would decrease the overall rate of cesarean sections for dystocia by only 15%. Physician convenience does not appear to be the major factor in the recent marked increase in rates of cesarean section for dystocia.

It appears, however, that there are several aspects of labor management in which the timing of physician intervention may have an important effect on rates of cesarean section for dystocia. As previously mentioned, elective inductions are associated with an increased rate.[5] Duff et al.[9] have shown that, in the patient at term with spontaneous rupture of the membranes, expectant management can significantly reduce rates of cesarean section for dystocia below rates that occur when such patients are induced. Further studies are required to determine the impact of artificial rupture of membranes, oxytocin stimulation (including its use in women whose labors are not well established), and continuous epidural analgesia on the progress of labor and rates of cesarean section for dystocia.

HOW TO SET UP AN IVF PROGRAM

"The Team Approach to In-Vitro Fertilization"

■ **June 10-14, 1987**
Harrah's Convention Center
Reno, Nevada

At this very special meeting, you can learn about planning, designing and establishing an IVF program.

This Serono Symposia, USA co-sponsored workshop will help teams of physicians, embryologists, nurse coordinators and psychologists develop a detailed approach to IVF.

Experts from three successful IVF programs will share their experiences through lectures and hands-on laboratory workshops and will lead general discussion sessions.

Plus, marketing professionals will discuss public relations and promotional strategies for IVF programs.

If you're interested in an IVF program, this may well be the most worthwhile meeting you can attend.

■ **Faculty**
Northern Nevada Fertility Clinic

PHYSICIANS:

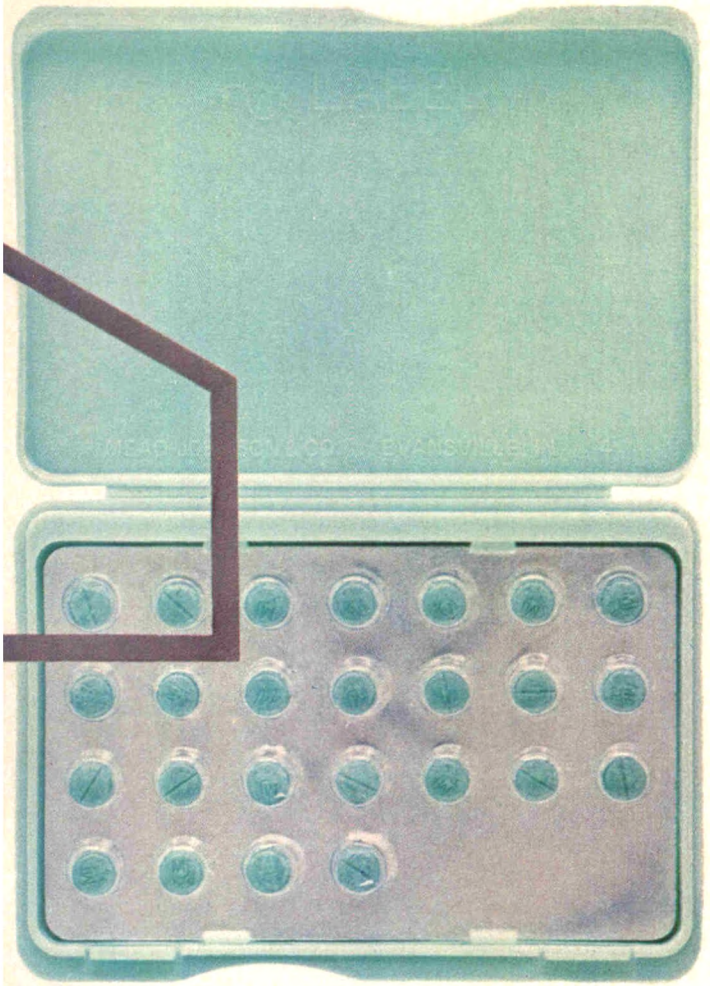
THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL—17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration. *Information for the Patient*—See text of Patient Package Insert. *Pregnancy Category X*—See Contraindications and Boxed Warning. *Nursing Mothers*—Administer to nursing mothers only when clearly necessary.

The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes.

For Prescribing Information, please see physician package insert.

PERINATOLOGIST/OBSTETRICIANS BOARD CERTIFIED OR ELIGIBLE

Virginia Baptist Hospital is seeking to employ an American trained perinatologist to establish a perinatal regional referral center. The perinatologist will administer the high risk referral system for both the region and private physicians.

Virginia Baptist Hospital has been proposed as one of the seven perinatal centers in Virginia. We average 2,500 deliveries annually and provide full neonatology services. The hospital is currently participating in a state grant serving a region comprised of nine counties with a population 450,000. The obstetrical services and the NICU were relocated in a new addition to the hospital in the fall of 1982 providing a complete scope of services from birthing rooms to cesarean section suite. In addition, Virginia Baptist Hospital is committed to providing a full spectrum of birthing options.

Virginia Baptist Hospital is a full-service JCAH accredited 384-bed hospital located at the foot of the Blue Ridge Mountains in Central Virginia convenient to summer and winter resorts and historic sites. Excellent benefit and salary package inclusive of professional liability coverage.

Submit C.V. to Dianne T. Nash, Vice President, Virginia Baptist Hospital, Rivermont Avenue, Lynchburg, Virginia, 24503 or call (804) 522-4521.

Instructor/Assistant Professor

Department of Obstetrics & Gynecology

Applicant must have completed an accredited residency in Obstetrics and Gynecology and a Fellowship in Reproductive Endocrinology or Maternal Fetal Medicine with special interest in Genetics and/or Sonography. Applicant will participate in students, Resident and Fellow training, clinical care of women at Parkland Memorial Hospital, and basic and clinical research. Must be eligible for Texas licensure. Interested persons send curriculum vitae to:

F. Gary Cunningham, M.D.
Professor and Chairman
Department Obstetrics and Gynecology
University of Texas Health Science Center
5323 Harry Hines Boulevard
Dallas, Texas 75235-9032

CHAIRMAN
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY
UNIVERSITY OF ILLINOIS COLLEGE OF MEDICINE AT ROCKFORD

We seek to appoint at a Professorial level, a Board Certified M.D. in Obstetrics and Gynecology, who will provide academic leadership, sound management and innovative programmatic conceptualization to the educational, research and service elements of our Department of Ob/Gyn. A clinical role is desirable, and in certain areas of specialization i.e. gynecological oncology, a regional opportunity exists through the OB/Gyn University Teaching Service, at our affiliate, Swedish-American Hospital. Applications should be received no later than May 1, 1987, with an anticipated starting date in September, 1987. Nominations and applications should be directed to Robert Klint, M.D., MHA, Chairman, Search Committee, University of Illinois College of Medicine at Rockford, 1601 Parkview Ave., Rockford, IL 61107.

The University of Illinois is an Affirmative Action/Equal Opportunity Employer

JMP-56

Maternal-Fetal Medicine

Hennepin County Medical Center and the University of Minnesota seek a faculty member to teach and conduct research in Maternal-Fetal Medicine. Candidates must have six years post M.D., board qualified or certified in Maternal-Fetal Medicine will be considered at the Assistant Professor level. Recruiting deadline is April 30, 1987.

Hennepin County Medical center and the University of Minnesota are equal opportunity employers and specifically invite and encourage applications from women and minorities.

Address inquiries to:

Bruce A. Work, Jr., M.D.
Professor and Head
Obstetrics and Gynecology
University of Minnesota
Box 395 UMHC
420 Delaware Street S.E.
Minneapolis, Minnesota 55455

CHAIRPERSON
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

The Knoxville Unit of the University of Tennessee College of Medicine is seeking a Chairperson for the Department of Obstetrics and Gynecology for the University of Tennessee Medical Center at Knoxville. This medical center is located in East Tennessee and is a 602 bed teaching hospital with research facilities. The position requires leadership ability and a record of commitment to patient care, education, and research. The applicant must be board certified in Obstetrics and Gynecology and possess the academic qualifications for Associate Professor or Professor.

Please submit your curriculum vitae to Edward Buonocore, M.D., Chairman, Ad Hoc OB/GYN Advisory Committee, University of Tennessee Medical Center at Knoxville, 1924 Alcoa Highway, Knoxville, TN, 37920.

An Affirmative Action/Title IX/Section 504 Employer.

CHAIRPERSON
DEPARTMENT OF OBSTETRICS/GYNECOLOGY

The University of Nebraska College of Medicine is searching for a Chairperson of Obstetrics and Gynecology. Applications are sought from board certified individuals with established credentials in research and demonstrated leadership in education. Interested applicants should submit a curriculum vitae by March 15, 1987 to: Chairman, Obstetrics and Gynecology Chairman Advisory Committee, Office of the Dean, University of Nebraska College of Medicine, 42nd Street and Dewey Avenue, Omaha, Nebraska 68105. The University of Nebraska is an Affirmative Action/Equal Opportunity Employer.

OBSTETRICIAN/ GYNECOLOGIST

The Smith-Glynn-Callaway Clinic, Inc., located in Springfield, Missouri, is seeking a physician university trained, board eligible or certified in obstetrics/gynecology to join its 66-physician, multispecialty group practice serving a regional population area of 1,000,000+. Competitive salary with bonus/production incentive. Fringe benefits package includes life, health, pension plan, vacation, paid meeting expenses. Four hospitals with combined bed capacity of 1,766. Excellent secondary schools, four universities. Please call or write to Administrator, 3231 South National, Springfield, MO. 65807 or call collect 417-883-7422.

GYNECOLOGIC ONCOLOGIST

The Allentown Hospital, with the 5th largest obstetrical service in Pennsylvania, is actively seeking a board certified or board eligible gynecologic oncologist for private practice and to provide leadership and medical education in gynecologic oncology.

The Hospital, a component of the HealthEast System, is located in the very desirable Lehigh Valley, in close proximity to all major East Coast cities. It sponsors a fully accredited OB/GYN residency program and has a major medical school affiliation. The Hospital co-sponsors a Comprehensive Community Cancer Center and offers a special interest gynecology group from multi-disciplinary specialties. There are no Board certified or Board eligible gynecologic oncologists in the Lehigh Valley, and the position provides a superb opportunity to establish a subspecialty practice and be integratly involved in a major regional teaching program.

Submit C.V. in complete confidence to:

Sze-ya Yeh, M.D.
Chairman, Department of Obstetrics/Gynecology
The Allentown Hospital
17th & Chew Streets
Allentown, Pennsylvania 18102
(215) 778-2412

MATERNAL-FETAL MEDICINE (Board eligible or Certified)

600 Bed University-affiliated Level III Hospital with 3,000 deliveries/year, 24-hour in-house anesthesiology and neonatology/large NICU, active maternal transfer service, perinatal outreach programs, and fully-approved OB/GYN residency program has immediate opening for a full-time position in perinatology. Duties to include residency teaching, maternal transfer care, and private practice incentive. Competitive guaranteed salary plus incentive. Excellent public school system, housing, and Lake St. Clair in very close proximity.

CALL COLLECT: 313-343-3495
SAINT JOHN HOSPITAL
DEPT. OB/GYN
DETROIT, MI 48236

OB-GYN

OBSTETRICIAN - GYNECOLOGIST wanted to join a progressive and prosperous three-man practice. Outstanding opportunity for a well-trained, Board-eligible, OB-GYN physician. This practice is string in High-risk Obstetrics, Infertility, Counseling, etc. Working out of a Level III hospital.

Send C.V. to:

Drs. Trabin, Manko, & Litt
1401 Forum Way #200
West Palm Beach, FL 33401
Phone: 305 689-8780

In intra-abdominal infection...

Consider

Fact No. 1

Bacteroides fragilis is the major anaerobic pathogen[1]

"The most common anaerobic organism is B fragilis, isolated in 80 to 95 percent of patients with colorectal perforation."[2]

Fact No. 2

Against *B fragilis*, CEFOTAN has equal in vitro activity to cefoxitin*[3-10]

Gorbach, Quintiliani, Neu, and others have studied a total of more than 900 isolates of *B fragilis* and determined that CEFOTAN and cefoxitin have equal in vitro activity.*[3-10]

Fact No. 3

Intra-abdominal infection is polymicrobial

Tally and Gorbach report that *B fragilis* is the major anaerobic pathogen, while *Escherichia coli* is the primary aerobic isolate

Fact No. 4

CEFOTAN has superior gram-negative activity compared with cefoxitin[12]

"...spectrum of activity [of CEFOTAN] is distinguished by having the same anti-anaerobe[†] effect as cefoxitin coupled with enhanced activity against Esch. coli and other Enterobacteriaceae."[13]

—C.J.L. Strachan–

*In vitro activity does not necessarily correlate with in vivo effectiveness.
†Most strains of *B distasonis*, *B ovatus*, and *B thetaiotaomicron* are resistant to CEFOTAN.

© 1986 ICI Americas Inc

The Facts

Fact No. 5 CEFOTAN is cost-effective

Twice-daily CEFOTAN can save 45% in treatment costs and single-dose prophylaxis with CEFOTAN saves 63% when compared with a three-dose regimen of cefoxitin.‡

Conclusion The facts now favor CEFOTAN

CEFOTAN is an ideal agent in the treatment of intra-abdominal infections due to susceptible pathogens including *Bacteroides* species such as *B fragilis*, but not *B distasonis*, *B ovatus*, or *B thetaiotaomicron*.

As active as cefoxitin against *Bacteroides fragilis*—the most common anaerobe in intra-abdominal sepsis—CEFOTAN provides superior gram-negative coverage and is particularly active against *E coli* and other common gram-negative pathogens.

In intra-abdominal infection due to indicated organisms Switch to

CEFOTAN® IM/IV
(cefotetan disodium)

The cost-effective replacement for cefoxitin

Please see the following page for brief summary of prescribing information.

‡Based on overall costs of antibiotic preparation and delivery[14] for comparable regimens: Treatment—CEFOTAN, 2 g × 2; cefoxitin,[15] 2 g × 4. Prophylaxis—CEFOTAN 2 g × 1; cefoxitin,[15] 2 g × 3.

CEFOTAN® IM/IV
(cefotetan disodium)

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

Maternal age and primary cesarean section rates: A multivariate analysis

Michelle Martel, M.D., Sholom Wacholder, Ph.D., Abby Lippman, Ph.D., John Brohan, B.Sc., and Emily Hamilton, M.D.C.M.

Montreal, Quebec, Canada

To study the effect of maternal age on primary cesarean section rates, 3458 consecutive deliveries were analyzed. The cesarean section rates in primiparous women less than 25, 25 to 34, and over 34 years of age were 13.1%, 18.5%, and 28.2%, respectively. A similarly dramatic rise with advancing maternal age was seen in multiparous women with rates of 3.4%, 4.7%, and 10.1%, respectively, in the three age groups. The strong association between cesarean section and maternal age persisted after multivariate adjustment for induction of labor, epidural anesthesia, meconium-stained amniotic fluid, and fetal distress, and thus these factors do not explain the relationship. (Am J Obstet Gynecol 1987;156:305-8.)

Key words: Cesarean section, primary; maternal age

Cesarean section rates have been increasing steadily in Canada, from 6.0% in 1970 to 17.1% in 1983.[1] Little consensus exists on the reasons for this increase. One suggestion has been that the increasing age of the obstetric population contributes to this trend.[2,3] Wadhera and Nair[1] reported a steady rise in the total cesarean section rate with maternal age. Nevertheless, because age-related primary rates are not available and because repeat cesarean sections, which would be more frequent among older women, are not excluded from most statistical summaries, the precise relationship between maternal age and cesarean section rates is unknown and explanations of it can only be speculative. This study was designed to analyze directly the effects of maternal age on primary cesarean section rates, taking into consideration other factors that might vary with maternal age.

Material and methods

All deliveries at the Sir Mortimer B. Davis Jewish General Hospital in Montreal, occurring from April 1984 to August 1985, were reviewed. After exclusion of those that were complicated by multiple gestation, stillbirth, placenta previa, or breech presentation and those in which cesarean section was performed because of a previous cesarean section, 3458 deliveries remained for analysis. These were grouped into three maternal age categories and according to whether the woman was primiparous or multiparous.

For each of the deliveries, information on the presence or absence of meconium, induction of labor, epidural anesthesia, fetal distress, maternal diabetes, hypertension, 1-minute Apgar scores, and birth weight was taken from the computerized delivery record completed at the time of delivery.

Various clinical methods are used to assess fetal health. Electronic monitoring of fetal heart rate was done in all patients in whom the diagnosis of fetal distress was made. Fetal scalp blood or cord blood samples were only rarely available. The antepartum diagnosis of fetal distress was made if there were persistent decelerations that may have been associated with changes in variability of the baseline fetal heart rate. Decreased variability alone was not considered fetal distress. The category of hypertension included all cases of hypertension requiring treatment and those in which the blood pressure was persistently >140/90 mm Hg in labor. The 1- and 5-minute Apgar scores were used to assess infants in whom the diagnosis of fetal distress was made. Because all cesarean sections for fetal distress were attended by neonatal staff, it was considered that the 5-minute Apgar scores would be influenced by resuscitation efforts and would mask the effect of fetal distress.

Analyses were performed separately for primiparous and multiparous women. Crude odds ratios were used as a preliminary measure of the association between maternal age and cesarean section. Because other factors related to maternal age and cesarean section could distort the association between these two variables, we carried out a multivariate logistic regression analysis wherein the dependent variable was presence or ab-

	Maternal age		
Indication	*≤24 yr*	*25 to 34 yr*	*≥35 yr*
Dystocia	0.8	1.6	5.0
Fetal distress	1.1	1.4	1.8
Abruptio placentae	—	0.2	1.1

Frequency expressed as percent.

sence of cesarean section and the independent variables were meconium staining of the amniotic fluid, induction of labor, epidural anesthesia, and fetal distress.[4] Adjusted odds ratio estimates were obtained from the regression coefficients of the model. These adjusted odds ratio estimates are free from the confounding effects of the other variables in the model. Diabetes and macrosomia were not themselves indications for cesarean section and therefore were not considered as covariates.

To investigate whether different diagnostic standards were applied to older women, we looked at the frequencies of low 1-minute Apgar scores, a marker of fetal distress, in the different age groups. If the diagnosis of fetal distress was applied similarly to women of different ages, the frequency of low 1-minute Apgar scores should be the same in all age groups among women undergoing cesarean section for fetal distress.

Results

Women aged 35 years and older constituted 10.9% of the total population, representing 5.8% of the primiparous women and 16.0% of the multiparous women. The overall cesarean section rate was 11.2% and the rates for each age-parity group are presented in Table I. There was a striking increase in rates in the primiparous women ($\chi^2 = 15.8$, $p < 0.0005$). Cesarean section rates were lower in the multiparous women, but there was still evidence of a significant increase with age ($\chi^2 = 12.2$, $p < 0.0005$).

Table IVA. Crude and adjusted* odds ratio estimates of the association between maternal age and cesarean section in primiparous women

†Compared with women under 25 years of age.

Table V. Frequency of 1-minute Apgar scores of ≤5 in infants of women having cesarean section for fetal distress

	Maternal age					
	≤24 yr		25 to 34 yr		≥35 yr	
	No.	%	No.	%	No.	%
Primiparous women	5/20	20.0	11/47	23.4	2/8	25.0
Multiparous women	1/3	33.3	4/17	23.5	1/5	20.0

A number of obstetric factors that may be associated directly or indirectly with a higher probability of cesarean section and their distribution according to maternal age are shown in Table II. As can be seen, there were no major differences in the frequencies of induction of labor, epidural anesthesia, or meconium in the various age or parity groups. Although fetal distress appeared to occur more frequently in the oldest age group, its relative rarity suggests that it cannot account for the increasing cesarean section rates.

Rates of dystocia among all of the age groups are presented in Tables IIIA and IIIB. It should be noted that dystocia is poorly defined clinically and the term is generally applied only when a cesarean section is performed. As a result it is not a useful covariate.

Dystocia, fetal distress, preeclampsia, and abruptio placentae were the major indications for cesarean section in this selected study population and their frequencies in the various age groups are shown in Tables IIIA and IIIB. These indications account for 84.5% and 71.0%, respectively, of all the cesarean sections in the primiparous and multiparous women. None of the other indications for cesarean section occurred in more than 2% of the women in this selected population.

Crude and adjusted odds ratios together with their standard errors are found in Tables IVA and IVB. For example, in Table IVA the crude estimate of the odds ratio in women aged 25 to 34 years shows them to be 1.5 times more likely to have a cesarean section than are primiparous women under 25 years of age. When the analysis is done by removing the effects of possibly confounding covariates, these same women are found to be 2.0 times more likely to have a cesarean section than are women under 25 years of age. The age effect is highly significant ($p < 0.0005$) for all of the analyses. The odds ratios are not substantially affected by the inclusion of the adjusting factors, suggesting that these factors alone or in combination do not explain the association between age and cesarean section.

The frequencies of low 1-minute Apgar scores among infants of women having a cesarean section for fetal distress were similar in the three age groups of primiparous and multiparous women (Table V). From this distribution, it would appear that fetal distress is being diagnosed similarly in the older and younger women even though it is more common among the older women.

Comment

Analysis confirms the association between maternal age and cesarean section rates, with dramatic increases seen among both primiparous and multiparous women. Results of multivariate analysis indicate that the increased rates are not an artifact resulting from the effects of the chosen covariates inasmuch as the adjusted rates do not vary substantially from the crude rates. In other words, even after adjustment for the covariates, the strong association between maternal age and cesarean section persists.

This analysis was restricted to variables available rou-

tinely from the delivery record. It is possible that unmeasured factors could explain the age and cesarean section association. These factors could include socioeconomic status, parental anxiety, or previous infertility, for example. It is unlikely, however, that they would include medical factors, since these would be subsumed in the chosen covariates.

It may also be that the increased rate in older women results from physician beliefs that this group is at increased risk for labor complications and that cesarean section can circumvent these problems. This is in agreement with the observations of Kirz et al.[5] More needs to be learned about how physicians make management decisions and whether these decisions are the most appropriate for older women.

Prenatal diagnosis and management of congenital defects of the anterior abdominal wall

M. Sermer, M.D., R. J. Benzie, M.D., L. Pitson, M.D., M. Carr, M.D., and M. Skidmore, M.D.

Toronto, Ontario, Canada

Between the years 1980 and 1985, 25 cases of anterior abdominal wall defects were identified within the University of Toronto Perinatal Complex. There were 17 cases of omphalocele and eight cases of gastroschisis. Associated anomalies were found in 71% of infants with omphalocele and 50% with gastroschisis. They were the major cause of neonatal death. Prematurity was the second most common cause of death. The neonatal death rate was 59% in omphalocele and 38% in gastroschisis; the prematurity rates were 53% and 50%, respectively. In omphalocele, there was a 47% cesarean section rate, with a 50% neonatal death rate. Vaginal delivery was associated with a 67% death rate. In gastroschisis, there was a 50% cesarean section rate, with a 50% neonatal death rate. Vaginal delivery was associated with a 25% death rate. There is no evidence that cesarean section offers improved neonatal survival. (AM J OBSTET GYNECOL 1987;156:308-12.)

Key words: Omphalocele, gastroschisis, prenatal diagnosis, ultrasound

The incidence of omphalocele is in the order of one in 4000 to one in 5000 live births, while that of gastroschisis is about one in 10,000 to one in 12,000 live births.[1, 2] Even though the incidence is relatively low, increased neonatal survival in the past decade has resulted in greater attention being paid to these congenital abnormalities.

These increased survival rates are secondary to advances within neonatal intensive care units, improvement in intravenous nutrition, better infection control, and development of new surgical techniques. For this reason, greater attention must be paid to the antenatal diagnosis, counseling, and management of these conditions.

Omphalocele is a defect of the umbilical ring and medial segments of the two embryonic lateral abdmonal wall folds. A sac is present into which intra-abdominal, and occasionally intrathoracic, contents may herniate. The inner layer of the sac consists of peritoneum and the outer layer consists of amnion. The umbilical cord insertion arises from the sac.

Gastroschisis is characterized by intestinal herniation through a defect in the anterior abdominal wall. This defect is usually to the right of the umbilicus. The um-

Table I. Omphalocele: Associated anomalies and neonatal outcomes

Case No.	*Chromosome analysis after amniocentesis*	*Associated anomalies*	*Outcome*
1	Trisomy 18	Patent ductus arteriosus, patent foramen ovale, renal dysplasia, craniofacial-skeletal anomalies	Neonatal death
2	Trisomy 18	Tetralogy of Fallot, scoliosis	Stillbirth
3	Trisomy 13	Atrial septal defect, ventricular septal defect, hypoplastic genitalia, craniofacial anomalies	Neonatal death
4	46,XX (17p-)	Cardiomegaly, neural tube defect	Died at 10 mo of congestive heart failure
5	Normal	Pulmonary artery stenosis, coarctation of aorta, undescended testicles, pulmonary hypoplasia	Neonatal death (respiratory failure)
6	Not done	Ectopia cardis, bifid ureter, hypoplastic lung, uterine anomalies, skeletal anomalies	Neonatal death
7	Not done	None	Neonatal death (respiratory distress syndrome, prematurity)
8	Not done	None	Neonatal death (respiratory distress syndrome, prematurity)
9	Not done	Meckel's diverticulum	Died at 31 days of bowel obstruction
10	Not done	None	Stillbirth (severe abruptio placentae)
11	Normal	Tetralogy of Fallot, pulmonary artery stenosis	Survived (respiratory distress syndrome)
12	Normal	Rectovesical fistula, short gut syndrome, imperforate anus, ambiguous genitalia	Survived (cardiac arrest)
13	Normal	Anal stenosis, cloacal exstrophy, ambiguous genitalia	Survived
14	Not done	Ileal atresia, blepharophimosis, syndactyly	Survived
15	Normal	Hypospadias	Survived
16	Normal	None	Survived (respiratory distress syndrome)
17	Not done	None	Survived

bilicus is not part of the defect. There is no sac covering the intestines. The intestines are thickened, edematous, and covered by an inflammatory exudate. These changes are thought to be secondary to the irritating effect of the amniotic fluid (pH 7.0).[3]

Ultrasound evaluation of omphalocele should include the assessment of the size of the sac and the entry of the umbilical vessels into the sac. Accurate assessment of the herniated organs should be made. In addition to intestines, organs that herniate may include the stomach, the liver, the spleen, and the heart. The umbilical cord enters the abdominal wall normally in gastroschisis. There is no sac present and the thickened intestines flow freely within the amniotic cavity. The herniated bowel will result in a cauliflower-like appearance.[4] Occasionally stomach and internal female genitalia may herniate as well.

The purpose of this article is to summarize our experience, review current literature, and then offer a reasonable outline for the prenatal diagnosis and management of these patients.

Method

A 5-year experience (October 1980 to November 1985) of four tertiary referral centers within the University of Toronto Perinatal Complex has been reviewed. Only the cases of abdominal wall defects in which it was elected to continue with the pregnancy were evaluated. Twenty-five cases were identified. Eight of these were transfered to the University of Toronto Perinatal Complex from outside centers.

Prematurity was defined as <37 completed weeks' gestation. Small for gestational age was defined as actual birth weight below the ninetieth percentile for the given gestational age.[5]

Results

A total of 25 cases of abdominal wall defects were identified (17 with omphalocele and eight with gastroschisis). None of the patients had prenatal serum levels of α-fetoprotein estimated. Ultrasound was performed in 65% (11 of 17) of cases of omphalocele and 75% (six of eight) of cases of gastroschisis. Of those that had prenatal ultrasound evaluations, the diagnosis was made in 64% (seven of 11) of the cases of omphalocele and 33% (two of six) of the cases of gastroschisis.

Associated anomalies were documented in 71% of infants with omphalocele and in 50% of infants with gastroschisis. The most common anomalies associated with omphalocele were: genitourinary, 47% (eight of 17); cardiac, 41% (seven of 17); chromosomal, 40% (four, only 10 tested); musculoskeletal, 29% (five of 17); gastrointestinal, 29% (five of 17); and central nervous

Table II. Gastroschisis: Associated anomalies and neonatal outcomes

Case No.	*Chromosome analysis after amniocentesis*	*Associated anomalies*	*Outcome*
1	Not done	None	Neonatal death (fetal distress, birth asphyxia)
2	Normal	Cleft palate	Neonatal death (respiratory distress syndrome, prematurity)
3	Not done	Large segments of small bowel atresia	Neonatal death (necrotic bowel)
4	Not done	Jejunal stenosis	Survived
5	Not done	Diaphragmatic hernia	Survived
6	Not done	None	Survived
7	Not done	None	Survived

No liver herniation	33	3/9

system, 6% (one of 17) (Table I). In contrast, there were only four anomalies in fetuses with gastroschisis. These were diaphragmatic hernia, cleft palate, jejunal stenosis, and small bowel atresia. The latter two are a complication of gastroschisis itself (Table II).

The neonatal death rate was 59% (10 of 17) in cases of omphalocele (six deaths due to associated anomalies, two due to prematurity, one due to obstetric complications, and one due to postoperative complications after repair of omphalocele) (Table I).

In omphalocele there were 12 cases with associated anomalies. Neonatal death occurred in seven, for a 58% death rate. No infant with a chromosomal anomaly survived. Six of seven infants with cardiac abnormalities died (four of the cardiac lesions were associated with chromosomal abnormalities). Two of five infants with gastrointestinal and four of eight infants with genitourinary anomalies died; however, these deaths were secondary to other associated conditions. Musculoskeletal abnormalities were seen in five cases, and four of these infants died. One infant with central nervous system abnormality died. However, these deaths were also secondary to other associated anomalies (Table I).

There were five cases with no associated abnormalities. Two infants died of prematurity and one died of severe abruptio placentae. The neonatal death rate in this group was 60% (three of five) (Table I).

There was a 38% (three of eight) death rate in cases of gastroschisis (one due to bowel atresia, one due to prematurity, and one due to an obstetric complication) (Table II).

In gastroschisis there were four patients with no associated abnormalities. Only one died, secondary to birth asphyxia (Table II).

The prematurity rates (<37 weeks' gestation) for omphalocele and gastroschisis were 53% and 50%, respectively. The infants were small for gestational age in 35% of cases of omphalocele and in 29% of cases of gastroschisis (Table III).

Table IV indicates that liver herniation is associated with an 88% (seven of eight) neonatal death rate in cases of omphalocele. Three patients, in addition to liver herniation, had the spleen, stomach, and heart within the omphalocele sac. In all of these cases neonatal death was recorded. Neonatal death was reported in one case of gastroschisis where the liver herniated.

In omphalocele, there was a 47% cesarean section rate, with a 50% neonatal death rate. Vaginal delivery was associated with a 67% death rate. In gastroschisis, there was a 50% cesarean section rate, with a 50% neonatal death rate. Vaginal delivery was associated with a 25% death rate (Table V).

Comment

This is a descriptive study of 25 cases of abdominal wall defects. None of the results obtained here showed a statistically significant difference, as measured by the 95% confidence interval or χ^2 test. Confidence in the results can be obtained only after prospective controlled trials are performed. Because of the low incidence of this condition such trials would be difficult to obtain and none are currently available. Nevertheless, some trends are becoming apparent from this article. Recommendations are based on these trends and

Table V. Mode of delivery and neonatal death rate

	Caesarean section		*Vaginal delivery*		*Total*	
	%	*n*	%	*n*	%	*n*
Omphalocele	50	4/8	67	6/9	59	10/17
Gastroschisis	50	2/4	25	1/4	38	3/8

on the information available from the current literature.

This study shows that the overall accuracy of identifying abdominal wall defects by ultrasound was only 64% for omphalocele and 34% for gastroschisis. Anomalies were missed in both the second and the third trimesters. This low detection rate is most likely due to the fact that some of these were routine ultrasound examinations performed at primary care centers. The value of detailed ultrasound, as an accurate tool in the diagnosis of abdominal wall defects, has been adequately documented.[3, 4, 6-8] A careful ultrasound examination cannot be overemphasized.

Ultrasound should be used to differentiate between the two conditions, by the well-established criteria.[4] The size of the lesion should be established, as excessively large lesions have been said to result in dystocia and rupture of the sac. More importantly, identification of herniated organs should be documented. In this study liver herniation in omphalocele was associated with an 88% neonatal death rate (Table IV). Spleen and heart herniation was associated with a 100% death rate. This finding is supported by Kirk et al.[10]

Ultrasound should be used to screen for other associated anomalies. In this study, 71% of cases of omphalocele were associated with other anomalies. Other large studies have reported slightly lower rates, between 29% and 66%.[1-3, 10-12] In this review, the only gastroschisis-associated anomaly that could be detected by ultrasound was diaphragmatic hernia.

Antenatal monitoring of the patients with continuing pregnancies should include serial ultrasound evaluations, not only to monitor abdominal wall defects but also to identify small for gestational age infants. The rate of small for gestational age in omphalocele was 35%; in gastroschisis it was 29%. Carpenter et al.[2] found 20% and 77% rates of intrauterine growth retardation in omphalocele and gastroschisis, respectively.

As there is an increased risk of premature labor and delivery, parents should be counseled about the possibility of premature labor so that appropriate monitoring and therapeutic measures can be instituted. The prematurity rate was about 50% in both omphalocele and gastroschisis. An increased prematurity rate was also noted by Grosfeld et al.[3] and Mayer et al.[13]

Omphalocele but not gastroschisis is associated with major chromosomal abnormalities.[2-4, 11-13] These were seen in 40% of patients where amniocentesis was performed. Neonatal death was recorded in all of these infants. Therefore, in cases where omphalocele is suspected, amniocentesis is indicated.

Major cardiac abnormality was seen in 41% of cases of omphalocele, an incidence comparable to that of others.[1-3, 12, 13] Cardiac abnormalities in gastroschisis cases are much less common. The highest rate was reported by Mann et al.,[12] where two of 16 patients had a cardiac anomaly. Others[2, 3, 13, 14] report rates of 0% to 8%. As the mortality rate associated with omphalocele and cardiac defect is 86%, fetal echocardiography should be performed. Further support for such investigation is offered by Crawford et al.[15]

In the past it was thought that cesarean section offered a better survival rate. For that reason several investigators elected to perform cesarean delivery in cases where abdominal wall defects were diagnosed prenatally.[16] Currently several authors[10, 14] have indicated that there is no clear evidence that cesarean section offers improved survival. Rupture of the sac is a relatively rare event and was seen in none of the omphalocele cases reported here. More importantly, neonatal death in all of the cases could be attributed to other complicating factors, mainly associated anomalies and prematurity.

In infants with no associated anomalies good outcome can be anticipated. This is particularly true of the infants with gastroschisis. These infants are still at risk of neonatal death secondary to prematurity, obstetric complications, and postoperative complications. Most common postoperative complications include aspiration pneumonia, sepsis, and small bowel obstruction and infarction.

Infants with abdominal wall defects should preferably be delivered in a tertiary pediatric center with surgical experience to correct these defects.

In conclusion, because of current medical advances, an increasing number of infants afflicted with abdominal wall defects are now surviving. For this reason it is important to identify prenatally those infants where a good prognosis can be anticipated. Where the prognosis is grave, because of the anomalies, a decision may have to be made about terminating the pregnancy.

Fig. 1 shows a suggested plan of management for abdominal wall defects. The maternal serum α-fetoprotein level has been shown to be elevated in abdominal wall defects.[12, 17] Differential diagnosis of elevated α-fetoprotein values, seen in patients who are being

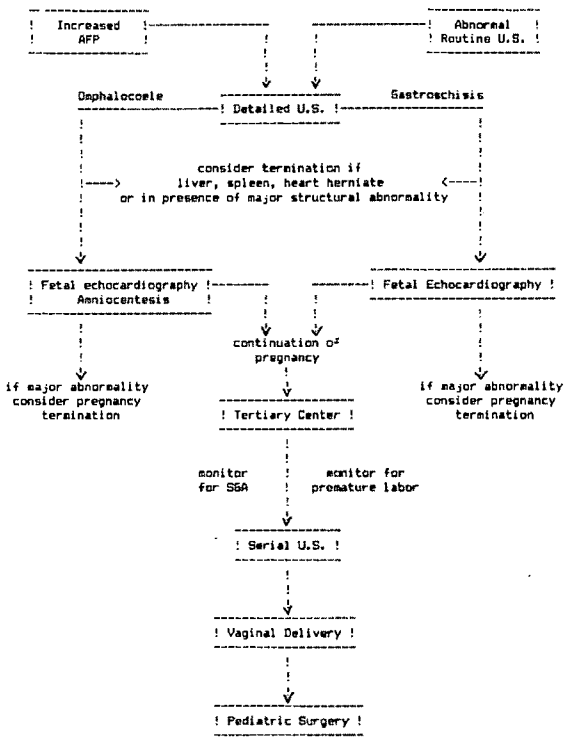

Fig. 1. Plan of management for abdominal wall defects.

screened for neural tube defects, should include abdominal wall defects. Detailed ultrasound should therefore be performed not only to look for neural tube defects but also to assess the integrity of the anterior abdominal wall. Herniated organs and other structural abnormalities should also be assessed. Termination of pregnancy should be considered in the presence of liver, spleen, and heart herniation.

Should routine ultrasound show the presence of abdominal wall defects a similar detailed ultrasound evaluation should be performed. Fetal echocardiography should be performed in both gastroschisis and omphalocele cases. Amniocentesis is indicated only in omphalocele. Should the pregnancy continue careful monitoring for premature labor and for appropriate fetal growth should be carried out. Delivery should be performed in tertiary care centers with appropriate pediatric backup. As there is no evidence that cesarean section offers improved survival, vaginal delivery should generally be performed.

Congenital heart disease in pregnancy: Short- and long-term implications

J. Shime, M.D., E. J. M. Mocarski, M.Sc., M.D., D. Hastings, M.D., G. D. Webb, M.D., and P. R. McLaughlin, M.D.

Toronto, Ontario, Canada

One hundred forty-four pregnancies that occurred in 74 patients with congenital heart disease at the Toronto General Hospital between 1975 and 1986 were reviewed. The patients were divided into two groups, those with acyanotic lesions and those with cyanotic lesions. Maternal and fetal outcomes in these two groups were compared. Patients with cyanotic lesions developed significantly more congestive heart failure and deteriorated more often in functional cardiac status than those with acyanotic lesions ($p < 0.005$). Women with obstructive lesions had a higher incidence of pregnancy-induced hypertension than our general population ($p < 0.005$). There was one maternal death in the puerperium in a woman with Eisenmenger's syndrome. Preterm births were more frequent in the cyanotic group ($p < 0.01$) as were small for gestational age infants ($p < 0.005$). In the cyanotic group the mean birth weight was 900 gm less than that in the acyanotic group ($p < 0.005$). The major benefits of corrective cardiac surgery were in the cyanotic group and consisted of fewer spontaneous abortions ($p < 0.01$) and small for gestational age infants ($p < 0.02$) and more term births ($p < 0.01$). Long-term follow-up revealed that 19.2% of women with acyanotic lesions had significant cardiac developments, compared with 90% in the cyanotic group ($p < 0.005$). One of 87 infants (1.1%) had congenital heart disease and two had Marfan's syndrome. (Am J Obstet Gynecol 1987;156:313-22.)

Key words: Congenital heart disease, heart, maternal, fetal

The ratio of rheumatic to congenital heart disease in pregnancy at the Toronto General Hospital has gone from 4:1 in 1962[1] to unity in 1985. This change can be partly attributed to an active adult congenital heart clinic that receives referrals from the adjacent The Hospital For Sick Children. In general, however, the declining incidence of rheumatic heart disease combined with advances in the surgical and medical management of congenital heart disease is responsible and reflects a global trend. Thus maternal heart disease, the leading nonobstetric cause of death in pregnancy, is changing and requires a reappraisal in terms of risks and management.

The following report documents our experience with congenital heart disease during pregnancy at the Toronto General Hospital from January 1975 to August 1986. Since the maternal physical condition will, at least in part, influence the ability to perform the tasks of motherhood, long-term evaluation of several patients has also been obtained. Finally, inasmuch as the offspring of these women are themselves at increased risk for congenital heart disease, all infants underwent examination for cardiac defects.[2]

Patients and methods

Seventy-four women with congenital heart disease had a total of 144 pregnancies. Cardiac diagnoses were established by angiography, echocardiography, or operation. The patients were managed by the obstetric staff in conjunction with the division of cardiology adult congenital heart disease clinic. There were 50 women with acyanotic lesions, subdivided into three groups: (1) obstructive: aortic stenosis, pulmonary stenosis, and aortic coarctation; (2) left to right shunts (ventricular septal defect, atrial septal defect, patent ductus arteriosus); and (3) miscellaneous.

Twenty-four women had cyanotic lesions and were subdivided as follows: (1) tetralogy of Fallot, (2) dextrotransposition or levotransposition of the great arteries, (3) tricuspid atresia, and (4) complex cyanotic.

All groups were further classified by operative status into group A, with surgical correction, or group B, uncorrected or palliative shunt. Nine women (seven with tetralogy of Fallot, two with dextrotransposition of the great arteries) rendered acyanotic by total corrective surgery are included with the cyanotic group. Outcomes have been compared for these nine women and the patients with unrelieved cyanosis.

Table I. Outcomes for individual acyanotic lesions

†Multiple anomalies.

During pregnancy, maternal cardiac and noncardiac complications were recorded and fetal outcomes documented. All neonates were examined for congenital heart disease. Long-term assessment beyond the last complete pregnancy, for women who gave birth (as opposed to those who aborted), was obtained by telephone interviews in conjunction with their most recent assessment in the congenital heart disease clinic. During follow-up we also questioned the mothers about any changes in the cardiac status of their offspring. Statistical comparisons were done by the χ^2 method unless otherwise indicated. We considered a p value of ≤ 0.05 to be significant.

Results

Tables I and II summarize the pregnancy outcomes for individual cardiac lesions. Overall, 144 pregnancies resulted in 52 abortions and 92 continuing pregnancies,

of which 87 have been completed and five are still undelivered. These five are excluded from all calculations except those concerned with the incidence of abortion. Inclusion in the latter calculations is appropriate because all five pregnancies have exceeded 20 weeks of gestation. Of the 52 abortions, 15 were spontaneous and 37 elective, of which 13 were for cardiac indications (Table III). There were 31 primigravid and 43 multigravid patients. Twenty-four pregnancies occurred in women under 20 years of age, 104 in women between 20 and 30 years, and 16 in women aged 30 years or more.

Maternal complications

Noncardiac complications (Table IV). Twenty-six noncardiac complications were recorded. Half of these were pregnancy-induced hypertension that included preeclampsia and acute-on-chronic hypertension. Thus in 87 completed pregnancies the incidence of pregnancy-induced hypertension was 14.9%. This is more frequent than the occurrence in our total obstetric population during the same period of time (4.3%, $p < 0.005$). Ten of the 13 cases of pregnancy-induced hypertension occurred in women with obstructive lesions, for an incidence in this group of 27.8%. When this incidence is compared with that of the rest of the study population, the difference is significant at $p < 0.01$. Three of four patients with corrected aortic coarctation had a biscuspid valve. These three also had residual hypertension that worsened during four pregnancies. In one of these, severe preeclampsia was accompanied by abruptio placentae, renal failure, and neonatal death at 28 weeks' gestation. One woman with dextrotransposition of the great arteries, corrected by the Mustard procedure, experienced an unusual course of pre-

eclampsia wherein progressive proteinuria (reaching 3.0 gm/24 hours) was unaccompanied by hypertension until 1 day before delivery, when the blood pressure rose to 150/95 mm Hg. The preeclampsia resolved in the early puerperium.

Delayed postpartum hemorrhage occurred in a woman with Eisenmenger's syndrome who was on a regimen of prophylactic postdelivery heparin therapy. The hemoglobin level fell from 183 to 114 gm/L. She required packed cells, fresh-frozen plasma, emergency curettage for removal of a small placental fragment, and finally estrogen therapy before bleeding ceased.

Cardiac complications (Table V). All patients were New York Heart Association (NYHA) functional class I or II at the outset, except for eight women with class III symptoms who underwent elective abortion. Of the 87 completed pregnancies, NYHA deterioration occurred in 23 (26.4%) and congestive heart failure in 10 (11.5%). In four patients, supraventricular arrhythmias developed; all were medically controlled. Functional deterioration occurred in 13 of 23 pregnancies (56.5%) in the cyanotic group compared with 10 of 64 (15.6%) in the acyanotic group ($p < 0.005$). Similarly, congestive heart failure was more frequent ($p < 0.005$) in the cyanotic group (seven of 23, 30.4%) than in the acyanotic group (three of 64, 4.7%). In most instances the degree of functional deterioration was mild to moderate, with three exceptions. The first, a women with Marfan's syndrome, had experienced two uncomplicated pregnancies. In her third pregnancy, at 38 weeks' gestation, she suffered aortic dissection that extended to the coronary arteries. Cardiac arrest ensued. She was resuscitated and underwent emergency cesarean delivery followed by immediate graft repair to the damaged arteries. The second patient was a woman with aorticopulmonary window and Eisenmenger's syndrome. Five hours after planned cesarean delivery for chronic fetal distress, she became hypotensive and cyanosis deepened. She experienced a cardiac arrest and died. Postmortem examination revealed blood in all serous cavities, leading to the speculation that a coagulopathy had contributed to her death. She was not receiving anticoagulants at the time.

In the third case, a women with severe aortic stenosis

Table V. Cardiac complications in continuing pregnancies

Complication	*Acyanotic lesions*		*p Value*	*Cyanotic lesions*

Aortic dissection	1/64	1.6	—	—	—

developed left ventricular failure at 30 weeks' gestation. At 38 weeks she had a fever of unknown origin that resolved with antibiotic treatment. One week later, while she was receiving antibiotics, she had a normal vaginal delivery. One month later she was readmitted to the hospital with infective endocarditis and recurrent cardiac failure. She required aortic valve replacement 5 months post partum.

One patient had postpartum infective endocarditis. A primigravida with corrected atrial septal defect and ventricular septal defect, she had not received preoperative antibiotics before emergency cesarean section for ruptured vasa praevia. The infection was treated with antibiotics and gradually resolved.

Maternal follow-up (Table VI). Fifty of the 74 women gave birth at least once. Twenty-six of 34 women with acyanotic lesions (76.5%) have been followed up. Of the 16 women with cyanotic lesions who were delivered, one died post partum. Ten of the remaining 15 women (66.7%) have been followed up. The duration of follow-up ranges from 3 to 112 months (average, 30 months). The patients were evaluated with respect to cardiac developments such as change in functional status and the need for further operation. Only five of 26 women (19.2%) with acyanotic disorders had important sequelae, compared with 9 of 10 women (90%) in the cyanotic group ($p < 0.005$). In the acyanotic group, two patients with atrial septal defect were scheduled for operation; one had an aortic valve replacement and another experienced NYHA functional deterioration. The patient with Marfan's syndrome was readmitted 3 months post partum with dissection of the abdominal aorta. In the cyanotic group, one patient with corrected dextrotransposition of the great arteries died of cardiac arrhythmia 18 months post partum. Two patients are awaiting Fontan procedures. Another developed infective endocarditis and, as well, recently underwent operation for repair of ventricular septal defect and conduit bypass of pulmonary artery stenosis; five have experienced mild to moderate NYHA class deterioration. In one of these, a woman with uncorrected tetralogy of Fallot, Eisenmenger's syndrome has developed.

Two patients, one with a porcine aortic valve (congenital atrial septal defect) and one with corrected tetralogy of Fallot, became pregnant again.

Duration of follow-up: <1 year, 4 (patients); 1 to 2 years, 18; 2 to 4 years, 8; >4 years, 6. Range of follow-up, 3 to 112 months (average, 30 months).

Fetal outcome (Table VII). There were 37 elective abortions. Thus 107 of 144 pregnancies have followed a natural course, including five undelivered pregnancies that (at this writing) have exceeded 20 weeks' gestation. In the acyanotic group, nine of 76 (11.9%) spontaneously aborted, compared with six of 31 (19.4%) in the cyanotic group. The perinatal mortality in the acyanotic group was 4.7% (three of 64) compared with 3.0% (three of 23) in the cyanotic group. The overall mean birth weight for infants in the acyanotic group was 3300 ± 600 gm compared with 2400 ± 800 gm in the cyanotic group ($p < 0.005$, Student's t test). Infants who were small for gestational age (neonatal weight less than tenth percentile for gestational age) were more frequent in the cyanotic group ($p < 0.005$) as were preterm births ($p < 0.01$). One neonate (1.1%) had congenital heart disease. Born to a mother with atrial septal defect, this infant died at age 4 weeks of cardiac failure resulting from coarctation. Two of three infants born to the patient with Marfan's syndrome have inherited this disorder.

Labor and delivery (Table VIII). The mean primary cesarean delivery rate was 21.8%, compared with the overall mean rate of 16% at the Toronto General Hospital during the same period. Although dystocia was

the commonest indication in the general population, it was no more frequently a reason for performing cesarean section than fetal distress (acute and chronic) or preeclampsia (with conditions unfavorable for induction of labor) in the study group.

Eisenmenger's syndrome (Table IX). Nine patients had a total of 19 pregnancies. Maternal and fetal complications were high in this group, which included the only maternal death. In particular, compared with incidences in the remaining patients in this study, preterm births and small for gestational age infants were significantly more frequent ($p < 0.005$).

Group A (surgical correction) versus group B (uncorrected or palliative shunt) (Table X). Groups A and B were compared with respect to cardiovascular and fetal outcomes in both the acyanotic and cyanotic groups. This assessment was not possible for each individual lesion because some patients (with uncorrected patent ductus arteriosus, uncorrected aortic coarctation) invariably underwent elective abortion and others (complex cyanotic) were confined to group B. Overall, the clearest demonstrable benefits derived from corrective surgery were seen in the cyanotic category where group A patients had a lower incidence of spontaneous abortion ($p < 0.01$) and small for gestational age infants ($p < 0.02$) and a greater achievement of term births ($p < 0.01$) than group B.

Comment

In women with congenital heart disease, pregnancy may be affected by (1) the functional cardiac status, (2) the anatomic diagnosis, (3) pulmonary hypertension, and (4) the type of operation and degree of residual impairment, if any.

Functional cardiac status. Maternal functional status is known to strongly influence outcome. Although only 20% of patients in this study are NYHA class III or IV, they account for 85% of maternal deaths.[3] Whittemore et al.[2] observed significant cardiac complications in 10% of women with class I or II symptoms, compared with 30% in women with class III or IV symptoms. Accordingly, in our unit women with class III or IV symptoms have been offered, and have accepted, pregnancy termination. Thus continuing pregnancies in this study were limited to women classified as NYHA I or II at the outset.

Reliance on functional status alone may, however, be

*Elective abortions excluded; undelivered pregnancies (n = 5) included only in calculations for spontaneous abortion.

misleading. Sudden and profound deterioration can result from anatomic deformities, hemodynamic alterations, or even therapeutic measures. Examples in our experience included aortic dissection, postpartum worsening of a right to left shunt, and delayed postpartum hemorrhage during treatment with anticoagulants.

Anatomic diagnosis. In the absence of pulmonary hypertension or large left to right shunts, women with patent ductus arteriosus, atrial septal defect, and ventricular septal defect usually tolerate pregnancy well, although uncorrected atrial septal defect and ventricular septal defect have each been associated with a maternal mortality of 5.5%[4] and fetal loss rates of 10% to 25%.[5] Maternal deaths have resulted from heart failure, infective endocarditis, or shunt reversal (after arterial hypotension or acute pulmonary hypertension secondary to pulmonic embolism). In the present study, 21 continuing pregnancies in women with left to right shunts resulted in four spontaneous abortions and 17 births, two of which were preterm. Two women with uncorrected atrial septal defects became pregnant while awaiting admission for corrective cardiac surgery. The first of these, with a 2.8:1 shunt, experienced a normal delivery at term. The second, presently 32 weeks pregnant, has a 4:1 shunt. The fetus is developing normally and NYHA status is stable at class II.

Women with pulmonic stenosis usually tolerate the increased right ventricular load seen in pregnancy. Although older data suggested an 8% incidence of cardiac failure,[4] more recently this complication occurred in only 2.8%.[2] Fetal losses vary but have been reported in as high as 20% of pregnancies.[5] We observed one spontaneous abortion, 10 live births, and no cases of cardiac failure.

Congenital aortic stenosis during pregnancy carries an increased risk of left ventricular failure, sudden death, and, particularly in the presence of a bicuspid valve, infective endocarditis.[6] Arias and Pineda[7] reported maternal and fetal mortalities of 17% and 32%, respectively, but their data included rheumatic valvular disease. Neilson et al.[8] reported no complications during 10 pregnancies in women with congenital aortic stenosis. In the series of Whittemore et al.,[2] 18 pregnancies occurred in women with left ventricular outflow obstruction and only fair or poor function. There were five instances of congestive heart failure and six of increased arterial blood pressure. Their data did not distinguish between aortic stenosis and aortic coarctation. We had 15 patients with congenital aortic stenosis. Excluding elective abortions, one of which was performed for class III symptoms, 21 pregnancies resulted in two spontaneous abortions, 19 term births, one neonatal death from aortic coarctation, two cases of cardiac failure, and five instances of pregnancy-induced hypertension.

In a literature review, Goodwin[9] reported a maternal mortality rate of 3.5% in pregnancies with uncorrected coarctation. Deaths usually resulted from aortic rupture or dissection (80% before labor and unrelated to the height of blood pressure), heart failure, cerebral hemorrhage, or infective endocarditis. Deal and Wooley[10] collected data on 185 pregnancies with uncorrected aortic coarctation in which no maternal deaths occurred. Blood pressure changes during pregnancy were characteristic of normal patients. Both studies noted a high fetal loss rate, possibly from diminished uteroplacental blood supply. Both of our patients with uncorrected aortic coarctation underwent elective abortion, one for severe systolic hypertension (>200 mm Hg) and the other after surgical clipping of a ruptured cerebral aneurysm. In the corrected group, four of seven pregnancies demonstrated pregnancy-induced hypertension, including one severe case with renal failure and neonatal death. These hypertensive changes contrast with the findings reported above.[10]

In young women, 50% of aortic dissections occur during pregnancy.[6] Szekely and Julian[6] described 15

cases, nine of which occurred in women with Marfan's syndrome and four in women with signs suggestive of this disorder. In susceptible women, pregnancy heightens the risk of aortic dissection or rupture by hemodynamic effects (widened pulse pressure, increased stroke volume) instead of by altered aortic histologic characteristics as was previously thought.[11, 12] Marfan's syndrome and pregnancy is a risky combination because (1) 50% of offspring inherit the disorder, (2) there is an increased risk of aortic dissection, and (3) there is usually a shortened life span (half normal), thus compromising the woman's ability to raise her child.[5] Reporting only one death in 26 pregnant women with Marfan's syndrome, Peyritz[13] concluded that the risk could be minimized by preconceptional echocardiography. He considered the low-risk patient to have minimal, if any, aortic root dilation and no aortic regurgitation or significant mitral valve dysfunction. Our own experience with one patient, however, exemplifies the risks stated above, in that two of her three children have Marfan's syndrome, the aorta of this patient dissected during pregnancy, and her present prognosis is grave because recently the abdominal aorta dissected.

Tetralogy of Fallot is the most common cyanotic congenital heart disease in adults and children today.[14] Uncorrected, it carries a 4% risk of maternal death and a 30% fetal mortality from hypoxia.[4] In pregnancy, the fall in peripheral vascular resistance increases the right to left shunt. Recurrent syncope, a hematocrit above 60, an arterial oxygen saturation below 80, and a right ventricular pressure above 120 mm Hg are poor prognostic factors.[6] Hypotension from blood loss or epidural anesthesia during labor and delivery can precipitate increased cyanosis and circulatory collapse. Two women in our series had uncorrected tetralogy of Fallot resulting in one elective abortion and one preterm birth. All six continuing pregnancies in women with corrected tetralogy of Fallot went to term with only one small for gestational age infant. Congestive heart failure occurred once in this group.

Data on other cyanotic lesions during pregnancy are scant. Collins et al.[15] described three cases of tricuspid atresia. The first experienced three spontaneous abortions, the second died in late pregnancy of massive hemoptysis, and the third was delivered prematurely of a 580 gm infant who died of immaturity in a pregnancy complicated by heart failure and pulmonary and cerebral emboli. We had one patient with tricuspid atresia and another with tricuspid atresia and a single ventricle. The former, after an unremarkable pregnancy, had a term small for gestational age infant. The latter had an uneventful maternal course but was prematurely delivered of a 1490 gm small for gestational age infant.

Six cases of a single ventricle and pregnancy have been reported and were reviewed by Stiller et al.,[16] who cited the following: maternal mortality, 16%; small for gestational age, 43%; preterm labor, 43%; cesarean deliveries, 70%. We had three patients with a single ventricle who had a total of five pregnancies and observed: maternal deaths, 0%; small for gestational age, 60%; preterm labor, 40%; and cesarean deliveries, 60%.

Neilson et al.[8] reported one case of a patient with uncorrected transposition of the great arteries who experienced two spontaneous abortions and one preterm neonatal death. Two of our patients had uncorrected dextrotransposition of the great arteries, one with a ventricular septal defect and one with Eisenmenger's syndrome. The former had one spontaneous abortion and one small for gestational age but term infant. She experienced congestive heart failure in the latter pregnancy. The other patient had one elective abortion. Two women with dextrotransposition of the great arteries corrected by the Mustard operation had a total of three pregnancies, which included one spontaneous abortion, one small for gestational age infant in a term pregnancy, and one normal term birth. Pregnancy-induced hypertension occurred in one patient and congestive heart failure in the other.

Pulmonary hypertension. This condition, as seen in Eisenmenger's syndrome, is associated with 35% maternal mortality, a 55% prematurity rate, a 30% small for gestational age rate, and 28% perinatal mortality.[14] The pathophysiologic cause of death is likely an increase in right to left shunting after a decrease in systemic vascular resistance from blood loss or epidural-related hypotension. These events favor increased cyanosis and hypoxia possibly compounded by pulmonary arterial stasis and thrombosis during the hypercoagulable postpartum state.[17] For patients in labor, Midwall et al.[18] demonstrated beneficial effects of high concentrations of oxygen that consisted of a fall in pulmonary arterial pressure and an increase in the ratio of pulmonary-to-systemic blood flow and the arterial oxygen saturation.

The use of heparin during the postpartum period to prevent intra-arterial pulmonary thromboses has not been shown to prevent deterioration and may indeed be hazardous,[17] as was the case in one of our patients who experienced a severe postpartum hemorrhage. In our experience, Eisenmenger's syndrome was associated with a high complication rate including one maternal death. However, this is a relatively low maternal mortality rate compared with those of other series[14] and may be attributed to some selection bias in that several of our more severely affected patients have accepted either sterilization or elective abortion (Table III).

Surgical correction. Because many congenital heart defects are now surgically correctable, a new population of women have reached adulthood and achieved pregnancy. Patients with corrected atrial septal defects, ven-

tricular septal defects, or simple coarctations appear to be undertaking pregnancy with no added risk.[14] Similarly, providing no residual impairment exists, women with corrected tetralogy of Fallot have excellent outcomes. Singh et al.[19] reviewed 40 pregnancies in 27 women with completely corrected tetralogy of Fallot and no residua. There were no abortions, premature births, small for gestational age infants, or serious cardiac complications. One neonate had pulmonary atresia. Whittemore et al.[2] observed that live births occurred in only 42% of pregnancies with unrelieved cyanosis. With palliative shunts there was a 72% live-birth rate but the infants were usually growth retarded. Total surgical correction was accompanied by a 78% live-birth rate with normally grown infants, results similar to our own.

Despite surgical advances, however, patients who have undergone palliative and corrective procedures continue to pose problems. Twenty-five years after palliative operation only 35% of patients are not disabled. A total of 10% to 25% of patients exhibit resting hypertension after correction of coarctation.[20] Other problems exist such as patch leaks, postvalvulotomy regurgitation, conducting system injuries, and blunted ventricular performance due to the effects of chronic volume and pressure overload, intraoperative ischemia, and scar formation.[21] Some of these problems were evident in the present study. Examples included postcoarctectomy hypertension, congestive heart failure in two women with corrected tetralogy of Fallot, and, possibly, a blunted pressor response in the patient with dextrotransposition of the great arteries, whose preeclampsia manifested primarily as proteinuria. This patient also experienced a supraventricular arrhythmia, a relatively common sequel to the Mustard procedure.

Congenital heart disease in neonates. Our incidence of 1.1% is low compared with the commonly quoted rates of 3% to 5% (and as high as 14%).[2] This may relate to the fact that in the absence of positive findings, our infants only underwent clinical evaluation. As well, only 73.5% of patients received long-term follow-up. In two of our telephone interviews, the mothers reported "murmurs" in the children, which had spontaneously disappeared. The high incidence quoted by Whittemore et al.[2] is undoubtedly related to a diligent search for cardiac lesions. In their series the most common defect was ventricular septal defect, and by age 3 years seven of 18 had spontaneously closed.

Therapeutic considerations. Before becoming pregnant, our patients with congenital heart disease are seen in the adult congenital heart disease clinic and the high-risk pregnancy unit. They have a careful clinical examination, electrocardiogram, chest x-ray examination, and in most instances echocardiographic evaluation. Most patients will have already undergone cardiac catheterization and many will have had surgical correction. They are apprised of the maternal and fetal risks associated with pregnancy. Cardiac surgery, where indicated (such as large left to right shunts, uncorrected tetralogy of Fallot, or aortic coarctation) should be performed before pregnancy is considered. Because the physical condition of the mother will, at least in part, influence her ability to perform the tasks of motherhood, the long-term prognosis is relevant to prepregnancy counseling and should be discussed in a sensitive but informative manner. In our study, cyanotic patients on the whole experienced more frequent cardiac sequelae ($p < 0.001$); however, other conditions such as Marfan's syndrome or symptomatic aortic stenosis carry an unfavorable prognosis. Thus each case must be individually evaluated.

Our current policy is to recommend against pregnancy or to offer elective abortion to patients with NYHA class III or IV symptoms and those with pulmonary hypertension. Patients with Marfan's syndrome should be similarly advised on both maternal and fetal grounds. Although the data on aortic coarctation are less clear, we believe that pregnancy should be undertaken only after corrective surgery and in the absence of significant associated defects such as bicuspid aortic valve or a gradient of >40 mm Hg across the coarctation. High-risk factors for patients with unrelieved cyanosis are discussed earlier with the data on tetralogy of Fallot. These patients should be told of their high predilection for delivering preterm small for gestational age infants.

Once pregnant, patients with congenital heart disease require a multidisciplinary approach involving the cardiologist, obstetrician, cardiac anesthetist, and neonatologist. All patients require increased rest periods, more frequent prenatal visits, and immediate treatment of acute illness such as respiratory tract infection or congestive heart failure. Iron therapy for prevention of anemia is important. Tailoring the management to specific needs is also essential. For example, patients with obstructive lesions should be closely monitored for pregnancy-induced hypertension, cyanotic patients for evidence of fetal dysmaturity, and those with Marfan's syndrome for signs of dissection. Similarly, while an agent such as propranolol might reduce the risk of aortic dissection in Marfan's syndrome, it would be contraindicated in women with significant aortic stenosis who must rely on an increased heart rate to achieve the cardiac output required during pregnancy. Fetal echocardiography, by allowing prenatal detection of a cardiac lesion, might expedite neonatal medical and surgical intervention when indicated.

Whenever possible we aim for vaginal delivery, reducing pain by controlled epidural anesthesia and minimizing bearing-down effects by shortening the second

stage. Other intrapartum measures include administration of oxygen, antibiotic prophylaxis (after delivery as well), and appropriate hemodynamic and electrocardiographic monitoring. Assessment of oxygen saturation and changes in shunt flow by arterial blood gases and/or finger oximetry are essential in patients with shunts. Hypotension induced by blood loss or epidural anesthesia must be rigorously avoided in women with shunts or significant aortic stenosis.

Postpartum patients at high risk, such as those with Eisenmenger's syndrome or critical aortic stenosis, must be initially managed in an intensive care unit. In the postnatal period, the relative risks of birth control measures, sterilization procedures, and future pregnancies should be discussed with the patient.

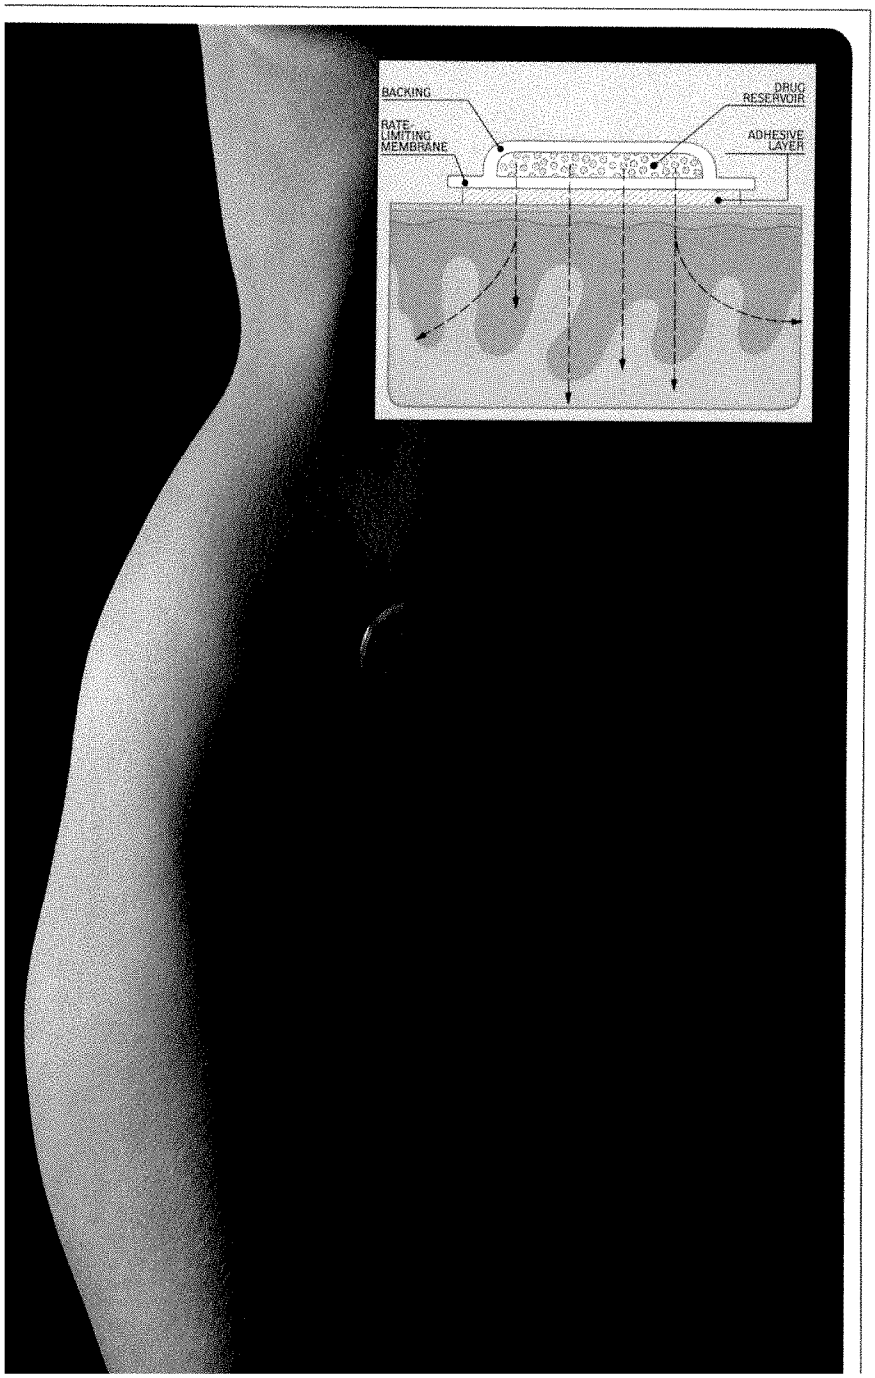
Now

The next generation of estrogen replacement therapy...

transdermal delivery



NEW

ESTRADERM®

estradiol transdermal syster

Combines the advantages of transdermal delivery...

A specially designed transdermal delivery system

Providing the natural ovarian estroge (17-beta estradiol) directly to the bloodstream and target organs; with no first-pass liver metabolism, permi use of extremely low dosage

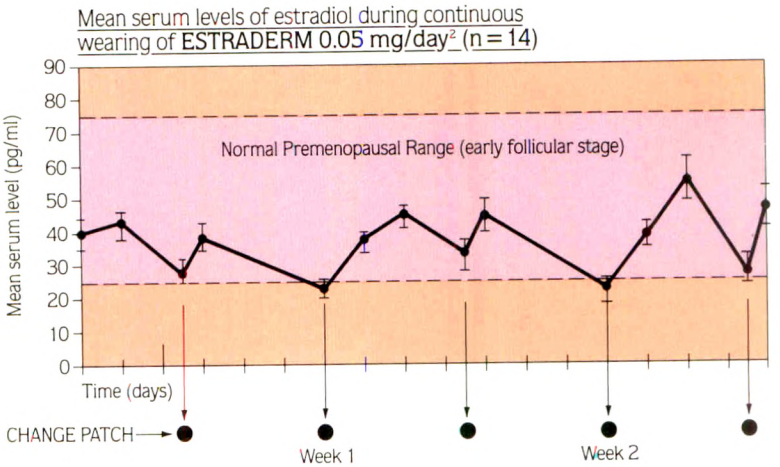
Effectively controls estrogen deficiency symptoms

Steady-state relief of hot flashes, oth menopausal symptoms associated wi hot flashes, and vaginal discomfort

Well tolerated

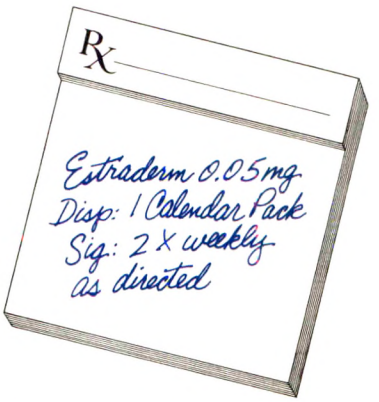
Very low incidence of systemic side effects...few local problems of consequence

Easy to use; transdermal delivery preferred 3:1 by patients over tablets[1]



Usual starting dose: a 0.05-mg syste changed twice weekly

C I B A



/ith the benefits of strogen replacement

:stores and maintains premenopausal tradiol serum levels

:tores estradiol levels to near-normal premenopausal ranges
chieves a physiologic 1:1 ratio of estradiol to estrone

ailable in dose-reminder calendar packs of eight
tches—0.05 mg/0.1 mg

: I B A
lping today's women live healthier lives

ESTRADERM®

estradiol transdermal system

Continuous delivery for twice-weekly application.
BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBINC INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than 1 year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

Studies of the addition of a progestin for seven or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of endometrium suggest that 12 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks that may be associated with the inclusion of progestin in estrogen replacement regimens. The potential risks include adverse effects on carbohydrate and lipid metabolism. The choice of progestin and dosage may be important in minimizing these adverse effects.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG) leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding; spotting; change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

Do not store above 86°F (30°C).

Do not store unpouched. Apply immediately upon removal from the protective pouch.

CAUTION: Federal law prohibits dispensing without prescription.

External vibratory acoustic stimulation near term: Fetal heart rate and heart rate variability responses

Robert Gagnon, M.D., Cora Hunse, R.N., Lesley Carmichael, B.Sc., Fraser Fellows, M.D., and John Patrick, M.D.*

London, Ontario, Canada

Twenty-five pregnant women between 36 and 40 weeks' gestational age were studied to examine effects of a 5-second external vibratory acoustic stimulus on the fetal heart rate and fetal heart rate variability. There was an immediate significant increase in the basal heart rate, which persisted for 1 hour after the stimulus, compared to that of the control subjects. There was also a significant increase in the total time during which accelerations occurred for the first 20 minutes after the stimulus. There were no changes in computer-derived indices of fetal heart rate variability. Maternal blood pressure and heart rate were not altered following vibratory acoustic stimulus. We hypothesize that external vibratory acoustic stimulus causes a change from a state of sleep to a state of wakefulness in near term healthy fetuses. (AM J OBSTET GYNECOL 1987;156:323-7.)

Key words: Nonstress test, external vibratory acoustic stimulation, effects of sound and vibration on fetal heart rate

The close association between human fetal heart rate accelerations and fetal health has been largely documented.[1-3] However, because healthy fetuses may be at rest for as long as 80 minutes, there has been a high false positive rate for nonstress tests performed over 20 or 40 minutes.[3] Use of external vibratory acoustic stimulus has been suggested to increase the reactivity of human fetuses.[4-5] We previously reported that the pattern in fetal heart rate was altered for at least 15 minutes following a 5-second stimulus with an electronic artificial larynx.[6]

The purpose of this study was to define, in a group of healthy fetuses near term, changes in fetal heart rate, fetal heart rate variability, maternal blood pressure, and heart rate after a standardized external vibratory acoustic stimulus.

Patients and methods

Patients. Informed consent was obtained from 25 pregnant women between 36 and 40 weeks' gestational age. Twenty-one women remained in good health, and four subsequently developed mild preeclampsia. Fetal outcome confirmed gestational age and the good health of fetuses studied. The average gestational age at delivery was 39.6 ± 0.2 weeks. The average weight of fetuses was 3373 ± 75 gm (SEM). The average 5-minute Apgar score was 9.3 ± 0.1. No Apgar score was <8 at 5 minutes. Umbilical cord blood gas values were determined in 18 of the fetuses. The average umbilical arterial Po_2 was 16.6 ± 0.9 mm Hg, Pco_2 was 49 ± 2.5 mm Hg, and pH was 7.27 ± 0.02. There were five cesarean section deliveries: one for cephalopelvic disproportion, one for development of acute fetal distress in labor with prolapsed cord (5-minute Apgar score of 8), and three repeat cesarean sections. Twenty-four fetuses were in vertex presentation and one in breech presentation at the time of delivery.

Experimental design. Women received a standardized 800 kcal breakfast or lunch at 8 AM (n = 15) or 12 noon (n = 13). All studies began an hour later and were conducted in a quiet room with patients either sitting upright in bed or resting in a lateral recumbent position. Women were asked not to smoke for at least 4 hours before the studies. Smoking or food intake by patients or observers was not permitted during the study.

All women had been acclimatized by listening to the stimulus in air before the beginning of the studies and were informed that the stimulus might be applied either on their abdomen or their hand. Three women had both control and stimulus studies, and observations were separated by >2 days.

The external vibratory acoustic stimulus used in this

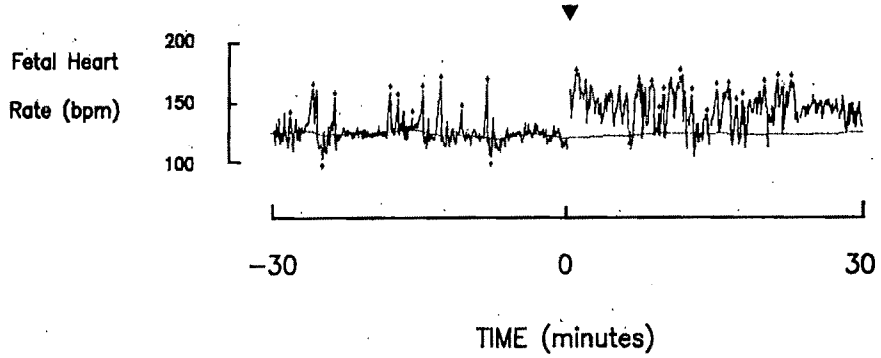

Fig. 1. A typical example of an increase in basal fetal heart rate and FHR accelerations following the application of a 5-second vibratory acoustic stimulus with the electronic artificial larynx.

study was generated with a Model 5C electronic artificial larynx (Western Electric, New York, New York, courtesy of Mr. John Kasper, Corometrics Medical Systems) as previously described.[6] The device produced a form of white noise between 10 and 10,000 Hz as measured in air at 1 cm from the generating source by a real-time spectrum analyzer (Brüel and Kjaer digital frequency analyzer, Type 2131). Maximum sound pressure level was 110 db at 10,000 Hz. The surface of the instrument vibrated at all frequencies between 10 and 20,000 Hz and maximum vibration occurred at 450 Hz (measurements made at 2 cm from the source with a Fotonic sensor, MTI Instruments Division). Women were studied continuously for 2 hours. After the first hour of observation, a 5 second vibratory acoustic stimulus with the electronic artificial larynx was applied on the surface of the maternal abdomen over the fetal head (n = 14) or on the maternal hand for control (n = 14). The choice of whether to stimulate the abdomen or hand of women was made from random number tables, and all women received only one stimulus to either abdomen or hand during individual studies.

Fetal and maternal cardiovascular measurements. Fetal heart rate was recorded with a Hewlett-Packard 8040A (Hewlett-Packard GMBH, Boeblinger, West Germany) external monitor with use of a compact transducer and was analyzed on-line by a microprocessor. The system consisted of a master 512K-memory microprocessor, Sage II (Sage Computer Technology, Reno, Nevada), and dual floppy disc drive, keyboard, and visual display unit as described by Dawes et al.[7] The Hewlett-Packard external monitor was interfaced with the microprocessor by a voltage/frequency converter, which was adjusted to generate a brief fast rising voltage pulse at intervals corresponding to the calculated heart rate. The fetal pulse intervals were examined with use of an artifact detection algorithm[8] and valid pulse intervals were averaged over 3.75 seconds. During analysis a baseline was fitted to the heart rate record as previously described,[9] and accelerations of >10 bpm for ≥15 seconds above the baseline were recognized automatically.

For each 10-minute interval the basal fetal heart rate (beats per minute), the root mean square (milliseconds) and the mean minute range (milliseconds) were calculated. The root mean square and the mean minute range quantify long-term fetal heart rate (FHR) variability.[7] To identify maternal cardiovascular effects, the maternal heart rate, systolic blood pressure, diastolic blood pressure, and mean arterial blood pressure were automatically recorded every 5-minute with a Dinamap (Model 845XT, Critikon, Inc., Tampa, Florida).

Fetal breathing movements and gross fetal body movements were measured with a real-time ADR ultrasound scanner (Model 2130, Advanced Diagnostic Research Corp., Tempe, Arizona) and were reported elsewhere.[10]

Data analysis. The basal fetal heart rate, number of accelerations of >10 bpm for ≥15 seconds above the baseline, duration and amplitude of individual accelerations, the total time spent in acceleration, the root mean square, and the mean minute range were determined for successive 10-minute intervals. Maternal heart rate and blood pressure were analyzed as mean ± SEM at 5-minute intervals. All other results are presented as means ± SEM for each 10-minute interval before and after either vibratory acoustic stimulus on the maternal abdomen (stimulus) or on the maternal hand (control) for the 2-hour observation periods. Portions of records that could not be analyzed because of signal loss of >30% were not included. These portions made up 2.1% of total study time.

Statistical significance between groups before and after stimulus or control was determined by use of a mixed nested analysis of variance (ANOVA) comparing overall means and each of the 10-minute intervals[11] with an HP 9845B microprocessor (Hewlett-Packard, Computer Division, Fort Collins, Colorado, USA).

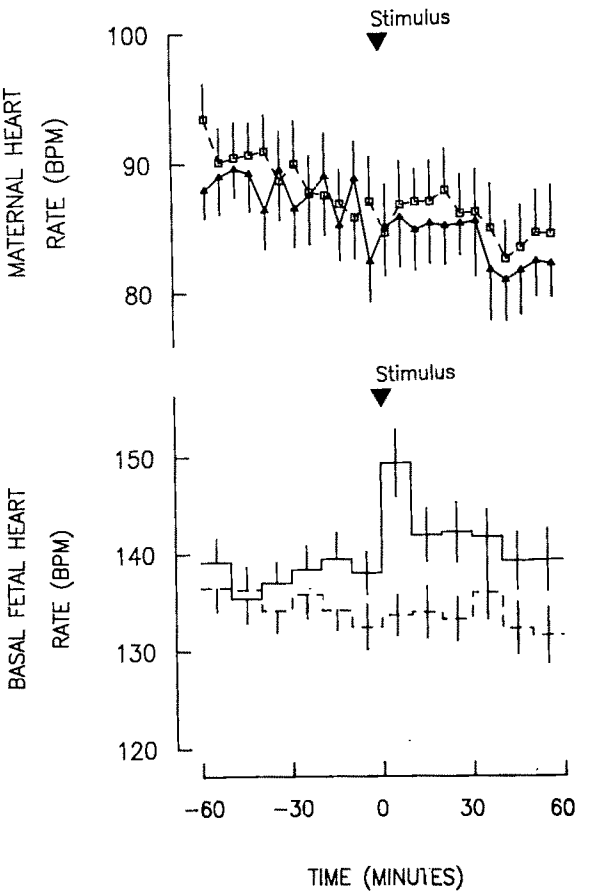

Fig. 2. The mean maternal heart rate was plotted in 5-minute intervals before and after control *(dashed line)* or stimulus *(solid line)*. The mean basal fetal heart rate was also plotted in 10-minute intervals before and after control *(dashed line)* or stimulus *(solid line)*.

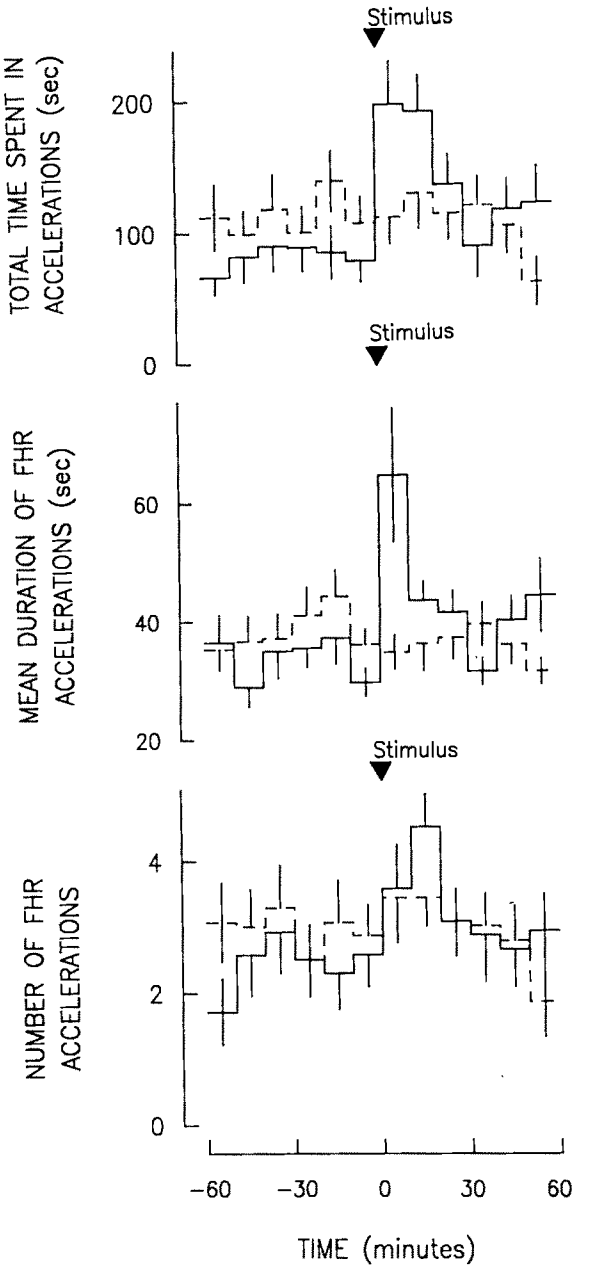

Fig. 3. The mean time spent in accelerations was plotted in 10-minute intervals before and after control *(dashed line)* or stimulus *(solid line)*. The mean duration of FHR accelerations and the mean number of FHR accelerations were also plotted on the same time scale.

Results

Fetal heart rate. A typical example of the FHR response to vibratory acoustic stimulus is seen in Fig. 1. Analysis of data demonstrated the mean basal FHR was 135 ± 2.1 bpm before control, which was not different from 138.4 ± 2.2 bpm before stimulus. There was an increase in the mean basal FHR during the hour after the stimulus of up to 142.1 ± 2.7 bpm, which was significantly greater than that after the control (Fig. 2) (ANOVA, $p = 0.017$). The maximum increase in basal FHR (149.2 ± 3.0 bpm) occurred during the first 10 minutes after the stimulus and remained above the control for the hour after the stimulus (ANOVA, $p = 0.0004$). During the control study the basal FHR decreased to 133.4 ± 2.2 bpm, which was similar to the decrease in maternal heart rate (Fig. 2).

Characteristics of FHR accelerations. Fig. 3 summarizes the characteristics of FHR acceleration responses per 10-minute interval before and after either control or stimulus. The total time per 10-minute interval during which accelerations occurred was 81 ± 10 seconds before the stimulus, and it increased to 142 ± 19 sec after the stimulus. ANOVA revealed there was a significant increase in the total time spent in accelerations during the first 20 minutes after the stimulus compared to control (ANOVA, $p = 0.0014$).

The mean duration of FHR accelerations (Fig. 3) was 33.0 ± 1.2 seconds during the hour before stimulus and 44.1 ± 2.2 seconds after stimulus. This was significantly longer than after control (ANOVA, p =

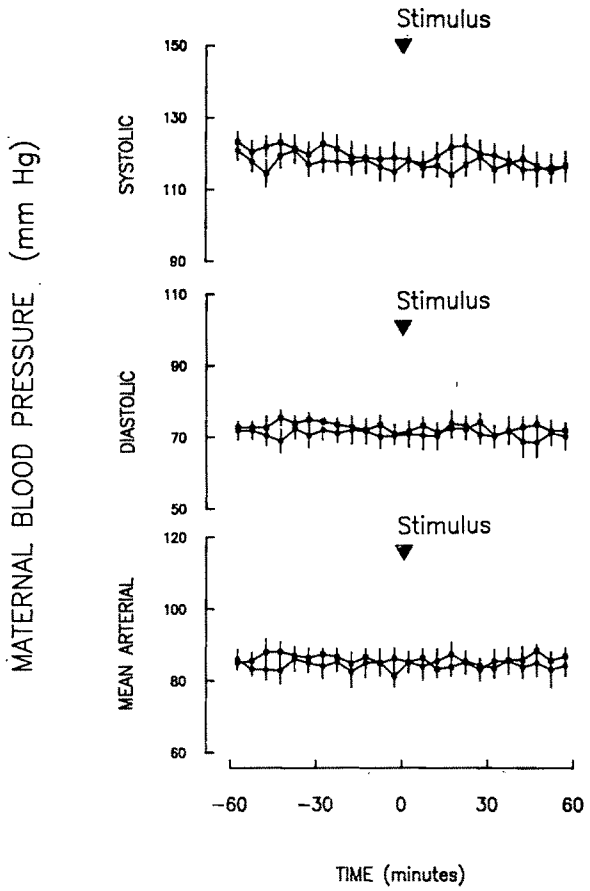

Fig. 4. The maternal systolic, diastolic, and mean arterial blood pressure was plotted in 5-minute intervals before and after control *(dashed line)* or stimulus *(solid line)*.

0.0031). ANOVA demonstrated a significant increase in the mean duration of FHR accelerations (64.5 ± 11.3 sec) during the first 10 minutes after the stimulus (ANOVA, $p = 0.0128$).

There were 2.5 ± 0.3 FHR accelerations per 10-minute interval before stimulus (Fig. 3), and ANOVA demonstrated a significant increase in the number of FHR accelerations between 10 and 20 minutes after the stimulus (ANOVA, $p = 0.0271$). All fetuses that received stimuli exhibited accelerations in the FHR between 10 and 20 minutes after vibratory acoustic stimulation.

The mean amplitude of FHR accelerations was 17.5 ± 2 bpm before stimulus and was not different in the 2 hours after either stimulus or control.

Fetal heart rate variability. The mean minute range per 10-minute interval was 44.6 ± 4.1 msec (range, 25 to 84 msec) and did not change after stimulus. The median root mean square value per 10-minute interval was 8.6 msec (range, 4.6 to 17.3 msec) before stimulus and did not change following vibratory acoustic stimulation.

Maternal blood pressure and heart rate. Fig. 4 demonstrates that systolic, diastolic, and mean arterial blood pressures were not changed by external vibratory acoustic stimulation. Mean maternal heart rate tended to decrease slightly during the experiment but was not significantly different before or after control or stimulus (Fig. 2).

Comment

This study made use of on-line analysis by a microprocessor that was able to quantify more accurately the different components of fetal heart rate. The results indicated that the pattern in the fetal heart rate after application of a vibratory acoustic stimulus on the surface of the maternal abdomen was altered for up to 1 hour after the 5-second stimulus. There was an increase of 11 bpm in the basal heart rate which began immediately after the stimulus and remained elevated above control for one hour after the stimulus. There was also a significant increase in the total time during which accelerations occurred in the first 20 minutes after stimulus which was due to (1) increase in the duration of FHR accelerations in the first 10-minute interval and (2) an increase in the number of FHR accelerations during the second 10-minute interval. The root mean square and mean minute range, which are measurements of long-term FHR variability, did not change. Similarly, maternal blood pressure and heart rate were not changed by the vibratory acoustic stimulus.

Prechtl et al.[12] studied term newborn infants and defined five different behavioral states that characterized sleep and wakefulness.[12] Dehaan et al.,[13] reported that in term neonates both heart rate and heart rate variability were increased during active sleep compared to quiet sleep. They also reported that during neonatal wakefulness the heart rate was higher but the variability was the same as during quiet sleep.[13]

The five states of sleep and wakefulness originally described in neonates are believed to take their origin in late fetal life in humans. Nijhuis et al.[14] with use of real-time ultrasound observed that fetuses of 36 weeks' gestation had developed states that were, in their organization, fully comparable to the states originally described by Prechtl et al. in neonates. Nijhuis et al.[14] described four different states, and one of these was characterized by a fetal heart rate with large and prolonged accelerations, often fused into sustained tachycardia. They believed these were periods of wakefulness. Patrick et al.[15] have defined the normal pattern of FHR accelerations was 40 seconds with a significant increase of up to 57 seconds between 11 PM and 2 AM coincidentally with an increase in the incidence of gross ncrease of up to 57 seconds between 11 PM and 2 AM coincidentally with an increase in the incidence of gross fetal body movements at this time period. This sort of pattern in healthy neonates is observed only during times of wakefulness and they speculated that human

fetuses at term may have prolonged periods of wakefulness in the late evening.

The FHR response to vibratory acoustic stimulation defined in this study was characterized by an increase in basal FHR and duration and number of FHR accelerations in the absence of changes in FHR variability. These observations would be compatible with the hypothesis that fetuses have been changed from a state of sleep to a state of wakefulness as a result of vibratory acoustic stimulation.

Schmidt et al.[16] reported that external controlled sound stimulation at 2000 Hz (120 db) of 5-second duration with a loudspeaker separated from the maternal skin by a ring of foam rubber failed to elicit any change in FHR or fetal body movement patterns.[16] Therefore the FHR response to vibratory acoustic stimulus in this study may be a result of stimulation by the vibrational component rather than the acoustic component of the electronic artificial larynx.

It remains to be determined whether a similar FHR response to stimulus with the electronic artificial larynx will occur in fetuses earlier in pregnancy. Data are also required regarding negative and positive predictive value for fetal outcome before suggesting any clinical application of the electronic artificial larynx in the evaluation of fetal health.

We wish to thank Professor G. S. Dawes and Mr. Isaac Rapoport for their kind assistance.

Psychological adaptation to pregnancy in childless women more than 35 years of age

G. Erlick Robinson, M.D., David M. Garner, Ph.D., Douglas J. Gare, M.D., and Belinda Crawford, B.Sc.

Toronto, Ontario, Canada

Forty-five pregnant childless women with a mean age of 36.6 years (±1.7) were compared with 42 nulliparous pregnant women with a mean age of 26.7 years (±2.8). Initial interviews determined the basic demographic data, the reasons for delaying pregnancy, attitudes to pregnancy, and plans concerning careers. Psychological tests were given to measure anxiety, depression, anger, marital intimacy, sense of autonomy, and role expectations. These psychological tests were applied to all patients at 12 to 16 weeks' gestation and again at 28 to 32 weeks' gestation. The demographic information from the two groups was remarkably similar. Although their ages differed by 10 years, their career goals, their family incomes, reasons for delaying pregnancy, and reasons for now getting pregnant revealed minimal differences. The Maffer Feminine Identity Scale revealed that the younger women held more traditional attitudes toward a woman's roles than the older group. The Sociotrophy-Autonomy Scale indicated that the older women were more independent than the younger pregnant patients. The Symptom Checklist indicated that the older group were less troubled by pregnancy than the control group, and although their level of distress increased as the pregnancy progressed, they remained better adjusted as they entered the last trimester of their pregnancies. (AM J OBSTET GYNECOL 1987;156:328-33.)

Key words: Elderly primiparas, pregnancy, psychological adjustment, emotional adjustment

In recent years, reliable methods of birth control and the changing roles of women have led to an increasing number of women postponing childbirth. In 1980, more than 13,000 women in their 30s gave birth to their first child; this represents a 94% increase since 1975. Previous research has focused on the psychological and social changes occurring in young primiparous women during this transition from childlessness to being a parent. Considering the trend toward postponing childbirth, it is surprising that there has been relatively little research into the psychological impact of giving birth at midlife. Baumann reported to the International Association of Psychosomatic Obstetrics and Gynecology that he had examined reasons for delaying pregnancy in a group of women of different ages and concluded that the older women were unconventional in the sense that a high percentage lived with younger partners. The main reasons reported for delayed childbearing were late acquaintance of the right partner and the wish to be free of responsibility. Unfortunately these women were interviewed only at the time of delivery, which may have influenced their recall of certain events.

A more detailed understanding of the pattern of adjustment in older primiparous women may lead to more specific recommendations to this group and, if they experience more psychosocial difficulties, it may result in more appropriate support during the pregnancy and the postpartum period. The aim of the present study was to examine with standardized psychometric measures the patterns of adjustment to pregnancy in a group of childless women who were 35 or older and compare them with a group of younger women who had never given birth.

Patients and methods

The present study was based on interview and psychometric data obtained in a group of 45 childless women over the age of 35 and a group of 42 women 30 years of age and under who also had never given birth. Both groups were interviewed initially between 12 and 16 weeks' gestation. The interview consisted of 30 questions to obtain demographic data as well as information concerning reasons for the timing of the current pregnancy, attitudes toward pregnancy, and plans concerning child care and work. In all cases permission to interview the women was obtained from the appropriate physician and written informed consent was acquired from the prospective mother.

Pregnancy planned	35	77.8	34	81.0	0.01	NS
Very satisfied with being pregnant	39	86.7	36	85.7	0.00	NS

Psychometric testing was then carried out on two occasions: The first session was before viability (at 12 to 16 weeks' gestation) and the second was between 28 and 32 weeks' gestation. The final groups did not include three women who refused to participate after the initial interview, 15 women who initially agreed to participate but did not return the first package of psychometric measures, and one woman who dropped out after initial testing. Of the women who completed the initial testing, one had a spontaneous abortion, one underwent abortion for genetic reasons, and another was excluded from the data analysis because her child was born with a serious birth defect.

At the initial contact the women were given a package consisting of the following questionnaires with the instructions to return them within 1 week: (1) the Symptom Checklist, which is a 90-item self-report measure designed to assess mood states including anxiety, depression, somaticism, hostility, phobia, obsessionality, paranoia, and psychoticism; (2) the Maffer Feminine Identity Scale, which is a 24-item scale that measures traditional and nontraditional sex role orientation; (3) the Social Intimacy Scale, which is a 20-item self-report measure of perceived intimacy with a significant other; (4) the Sociotropy-Autonomy Scale, which is a self-report personality measure that provides scores for social dependence (the degree to which social relationships are perceived as important) and autonomy (the degree to which independent pursuits are perceived as important).

On the second testing occasion, the women were sent a package of self-report measures in the mail with instructions to return them within 1 week. The following measures were completed: (1) the Cranley Maternal-Fetal Attachment Scale, which is a 24-item measure with five subscales (role taking, differentiation of self from the fetus, interaction with the fetus, attributing characteristics to the fetus, and giving of self) designed to assess the degree of maternal bonding toward the fetus; (2) the Symptom Checklist; and (3) the Social Intimacy Scale described above.

Data analysis. Group differences on categorical variables were analyzed with the use of the χ^2 statistic and Fischer's correction, where appropriate. Continuous variables were exposed to a two-way analysis of variance (group × testing occasion) except when measures were administered only once, and then variables were compared with the use of Student's t test (two-tailed).

Results

As expected, there were age differences between groups (older, mean = 36.6 ± 1.7; younger, mean = 26.7 ± 2.8; $t = 19.54$, $p < 0.0001$); however, there were no differences between groups in the number of years married (older, mean = 4.1 ± 4.1; younger, mean = 3.4 ± 2.3). Similar proportions of the two groups of women had careers (older, 50.0%; younger, 28.2%; $\chi^2 = 3.24$, NS), incomes greater than $25,000 (older, 55.6%; younger, 43.6%; $\chi^2 = 0.77$, NS), and partners with incomes greater than $25,000 (older, 78.6%; younger, 66.7%; $\chi^2 = 0.96$, NS). Significantly more of the older women (62.2%) than the younger group (38.1%) had a university education ($\chi^2 = 4.14$, $p < 0.05$). The older group had significantly more dif-

*High score indicates more traditional values.

ficulty conceiving with 1.1 (±2.4) years' delay versus 0.3 (±0.7) year for the younger group (t = −2.18).

With regard to obstetric performance, the duration of labor, Apgar scores at 1 and 5 minutes, weights of newborn infants, and neonatal course of the infants, there were no statistically significant group differences. Three significant perinatal problems occurred in the younger or control group, and these included one case of bilateral talipes equinovarus, one case of pneumothorax with pneumomediastinum, and a case of duodenal atresia. Similarly there were three significant neonatal problems in the babies delivered of mothers over age 35. These included a ventricular septal defect, which was repaired, a cleft palate, and one case of osteogenesis imperfecta.

As indicated in Table I, various reasons were given for delaying pregnancy in the younger and older groups. In the older group, the majority claimed that they had not had a suitable partner, less than a quarter stated that both partners were not yet ready to have children, and just over 15% identified infertility as the reason for delaying pregnancy. In the younger group, the most common reason for delaying concerned both partners not being ready for children followed by financial constraints. The majority of both the older and the younger women reported that they were satisfied with the pregnancy and that the event had been planned. The most common reason for becoming pregnant in both groups was emotional readiness followed by finding a suitable mate for the older group and financial feasibility for the younger group.

The history of previous pregnancies indicates that 20 elderly primiparous women and 16 younger primiparous women had previously had at least one abortion. In these subgroups, elective abortion was the most common (45.0% in the older subgroup and 56.3% in the younger subgroup), but spontaneous abortions were also common (40.0% of the older group and 37.5% of the younger group). Of the 11 older primiparous women who had had multiple abortions, 36.4% had been elective and 54.5% spontaneous. Only two of the younger women had had more than one elective abortion.

The results of the two groups of women on both the Maffer Identity Scale and the Sociotropy-Autonomy Scale were compared with *t* tests, with a Bonferroni-type adjustment used to control for Type I error due to the multiple comparisons. The younger women had significantly higher scores than the older women on the Maffer Feminine Identity Scale, indicating that the younger women had more traditional views. The younger women were significantly more sociotropic than the older women, particularly with respect to attachment to others or concern about separation, while the older women were more autonomous than the younger women, especially on the preference for solitude factor. The Cranley Maternal-Fetal Attachment Scale was administered only at 28 to 32 weeks' gestation and there were no significant group differences on four of the five subscales; the younger group had higher scores on the Differentiation Subscale (older, mean = 15.9 ± 2.7; younger, mean = ±2.1; t = 2.32, p = 0.03) (Table II).

The Symptom Checklist and the Social Intimacy Scale were administered at 12 to 16 weeks' gestation and at 28 to 32 weeks' gestation. These data were subjected to analysis of variance with one between-subjects factor (age) and one within-subjects factor (stage of gestation). There were no significant group or time differences on the Social Intimacy Scale. As indicated in Table III, there were group, time, or interaction effects on most of the Symptom Checklist subscales. There were significant time of gestation effects for somatizing, obsessive-compulsive, depression, anxiety, and psychoticism subscales with both groups of women reporting more symptoms at the second testing than at

the first testing. The younger women displayed significantly more distress than the older women on somatizing, interpersonal sensitivity, depression, anxiety, hostility, and phobia scales. There were no significant group-by-time interactions except on the depression subscale, indicating that the older women increased in depression over time while the younger women did not; however, at the second testing the older women were still less depressed than the younger women. The total scores on the Symptom Checklist are summarized in Fig. 1, which indicates that both groups became significantly more distressed over time and that the younger women overall report more distress than the older women.

Comment

A woman's psychological adaptation may influence the course of pregnancy, the labor and delivery, and the postpartum period. Emotional disorders in pregnancy have been related to low self-esteem, previous psychiatric history, being unmarried, marital problems, and environmental stresses. Negative attitudes during pregnancy have been shown to be related to intense pain and higher levels of medication during labor. These findings are supported by McDonald,[1] who found a positive correlation between anxiety and labor length.

Blum[2] retrospectively compared the pregnancies of 55 elderly primiparous women with those of two groups of primiparous women aged 20 to 29 and 30 to 34 and found that the older women were more careful during pregnancy and consulted their physicians more often. Zajicek[3] found that the younger women in his study were more likely to experience psychiatric problems both before and after birth, but 47% of his younger group were teenagers when they became pregnant. In contrast, Hayworth et al.[4] found that younger women and women who perceived themselves as less in control of their lives were more likely to be depressed postnatally.

Previous research provides few insights into the degree to which observations derived from younger primiparous women may be generalized to women who have their first child somewhat later in life. Older women who become parents for the first time may differ from younger women in many ways. They may be more financially stable and independent. They may have already established careers that have added to their sense of self-esteem, maturity, and role identification. Moreover, careers may be greatly influenced by the presence of a child. Having had relative freedom or the presence of only a dyadic relationship for many years, the woman may have difficulty adjusting to the increased ties and responsibilities of a child. The hus-

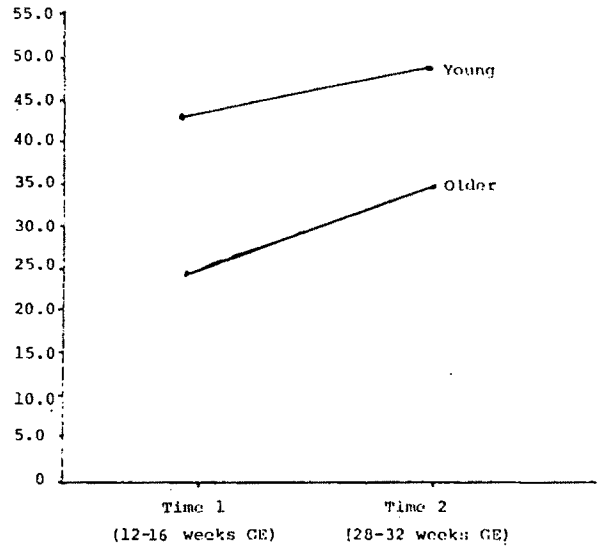

Fig. 1. Total score on the Symptom Checklist for older and younger childless women. A two-way analysis of variance demonstrated a significant group effect ($p \leq 0.01$) and a significant time effect ($p \leq 0.007$).

band may have had a longer period of accepting the present sex role of his wife and may not expect her to suddenly shift to a more traditional pattern.

The results of the current prospective study indicate that the older group of pregnant women make a relatively positive adjustment to pregnancy. At 3 and 7 months before delivery they demonstrate less distress than the younger women as measured by the Symptom Checklist. There are certain limitations that must be noted concerning group selection since it was not possible to randomly allocate women to groups that would have a first child in their 20s versus those who would wait until they were 35 or older. Thus it is not possible to conclude that women who wait longer to have children will fare better during pregnancy. It may merely indicate that women who delay pregnancy are a different and perhaps more robust group than those who choose to have their children earlier in life.

Moreover, the degree to which the two groups are representative of the general population is unknown. Both of the studied groups tend to be from the middle or upper-middle class socioeconomic strata. The younger women were obtained from the practices of physicians working in a large, university-affiliated metropolitan hospital. Although some of the older women were drawn from practices of the physicians at the hospital, many of the women were referred to the amniocentesis clinic of the hospital; the degree to which selection based on willingness to undergo amniocentesis affected the findings is uknown. It is quite plausible that women who delay pregnancy do tend to come from higher socioeconomic groups. Nevertheless, the fact that the groups were well matched in terms of most of the demographic factors allows us to compare the effects of differences in age without the influence of factors that have previously been shown to be associated with distress during pregnancy such as low social class and economic problems.

In the current study the reason most often reported by the older women as reponsible for delaying pregnancy was lack of a suitable partner. For some of them, this meant not having previously been married, whereas for others it meant having had an unsatisfactory earlier relationship. It is interesting to note the high degree of planned pregnancies in our two groups (77.8% and 81.0%). Other authors have found a lower percentage of planning in their samples: 41%,[5] 33%,[6] and 52%.[7] The relationship between planning a pregnancy and successful adaptation to pregnancy is not clear. Shereshevsky and Yarrow[8] found that planning was not related to adaptation to pregnancy, and Entwisle and Doering[9] found it not related to the woman's attitude toward being pregnant. On the other hand, Zajicek[3] found that women who did not plan their pregnancies were less likely to react positively throughout the pregnancy. Lederman[1c] also found that women who had planned or wanted their pregnancy were well adjusted.

A number of authors have commented on the change in women's roles associated with having a child. Gordon et al.[11] found that abnormal emotional reactions to pregnancy were related to a maternal role conflict, which indicated that mothers were prepared for social, educational, and economic advancement outside the home but not for the maternal role. Lederman[10] described conflict being acute if the need to be a mother and the need to identify oneself as a career woman were both felt intensely. The findings of the current study indicated that the younger group held more traditional attitudes than the older women, which may simply corroborate the fact that the older group was less traditional by virtue of their delaying of pregnancy. This explanation is weakened by the fact that there were no group differences in terms of numbers of years married, career, or income. Nevertheless, more of the older group had attended a university. These results may be confounded by an overrepresentation of Catholic women in our younger group and these women may have more traditional values. At the same time it may also be that there is a return to more traditional attitudes in many younger women as they see the stress that other women are going through in terms of career and home conflicts. It will be important to determine whether these role attitudes change after the birth of the baby. Consistent with the findings concerning role behavior, the findings from the current study indicated that the older women were more autonomous than the

younger women. Other authors have described the importance of autonomy in older women with careers. It may be that older women as a whole are more autonomous than younger women or that the older women in the current study were more autonomous and therefore chose to become pregnant later.

Many authors have written about the importance of the relationship with the husband in terms of affecting both the course of pregnancy and the postpartum adjustment[8] and even the duration of labor and the need for sedation.[10] Dyer[12] and LeMasters[13] focused on the impact of the coming of a first child on the marital relationship. Both felt this generated crises in the marriage forcing each couple to reorganize many of their roles and relationships. The measure of social intimacy used in the current study failed to reveal significant effects for the women over time. It will be interesting to note if marked changes occur postnatally.

The findings of the current study are consistent with those of other authors who have found increasing psychological tension during the last trimester of pregnancy as women start to face the imminence of labor and birth.[8] The younger group in the current study showed elevated levels on the depression scale at initial testing with only a slight increase on the second testing occasion, which may indicate a ceiling factor of their level of depression rather than an actual differential change in depression between the two groups. However, it cannot be assumed that the younger group are more distressed than nonpregnant women of a similar age. It has been concluded from some studies that women of this age generally have a higher degree of symptom levels than older women. For example, in studies of younger women, Weissman and Klerman[14, 15] have found high levels of depression and Griffith[16] has found increased stress levels, which she hypothesized are pressures associated with heightened expectations and role conflicts in the absence of realistic role models in contemporary society. Younger women may also suffer from more unrealistic optimism and high expectations whereas older women either have achieved valued expectations or place less emphasis on attaining them. It may be that the results of the current study reflect simply the effects of age irrespective of the effect of the pregnancy. However, it is important to note that older childless women do not appear to be unduly distressed during pregnancy despite a perhaps more major change related to this pivotal event in their lives. Not withstanding the greater danger of congenital defects, these women are less symptomatic in the early months of pregnancy. Neither is their continued better adjustment merely the result of the reassurance obtained by having amniocentesis as their depression level still rises over the course of pregnancy.

The postpartum follow-up of these women will elucidate factors during the prenatal period that help to predict outcome. Such predictive factors would then allow preventative measures to be designed to help women who may be vulnerable to problems in the postpartum period.

The Canadian Psychiatric Research Foundation provided support for the pilot project, and The Hospital For Sick Children Foundation and Bell Canada are providing ongoing support.

Shoulder dystocia: Predictors and outcome

A five-year review

Susan J. Gross, M.D., Jerry Shime, M.D., and Dan Farine, M.D.
Toronto, Ontario, Canada

Shoulder dystocia is an uncommon complication of delivery with a high morbidity rate. Ninety-one cases were coded for shoulder dystocia at the Toronto General Hospital from 1980 through 1985. True shoulder dystocia was found in 24 cases, an incidence of 0.23%. There was no significant difference in average weight and percentage of macrosomia between cases of true shoulder dystocia and those merely coded as such. True shoulder dystocia was associated with a neonatal morbidity rate of 42%, consisting of a respiratory arrest and neurological and orthopedic damage. Fundal pressure, in the absence of other maneuvers, resulted in a 77% complication rate and was strongly associated with orthopedic and neurologic damage. Delivery of the posterior shoulder and the corkscrew maneuver were associated with good fetal outcome. (Am J Obstet Gynecol 1987;156:334-6.)

Key words: Shoulder dystocia, complications, obstetrics, delivery maneuvers

Although shoulder dystocia is an uncommon complication of delivery with a suspected incidence of 0.15% to 0.3%,[1] it is associated with a relatively high morbidity rate of 16% to 48%[2, 3] and potentially devastating outcome.

The risk factors for shoulder dystocia are often seen with macrosomia (birth weight of >4000 gm) and include multiparity, postdatism, previous macrosomic infant, and obesity. Diabetes carries a twofold risk of shoulder dystocia that is due to a combination of macrosomia and altered body configuration.[4, 5] Prolonged second stage of labor and midforceps delivery (alone and in combination),[3] as well as protraction and arrest disorders,[6] have also been identified as risk factors for shoulder dystocia.

True shoulder dystocia refers to deliveries requiring maneuvers to deliver the shoulders in addition to downward traction and episiotomy.[1] The following study documents our experience with shoulder dystocia during a 5-year period. Deliveries complicated by true shoulder dystocia were compared to deliveries that were merely coded as such. The risk factors listed above were compared in these two groups. Management of shoulder dystocia and its relationship to fetal outcome and maternal morbidity were analyzed as well.

Material and methods

All vaginal deliveries (10,662 cases) performed at the Toronto General Hospital from April 1980 to March 1985 were analyzed retrospectively. There were 91 deliveries coded for shoulder dystocia; 24 were cases of true shoulder dystocia (group 1); and the remaining 67 cases, although coded as shoulder dystocia, merely required increased traction for delivery (group 2). Risk factors for shoulder dystocia were compared in both groups, with prolonged second stage referring to >1½ hours for a multiparous patient and >2 hours for a primiparous one.[7] Maternal and fetal outcome were also compared. Fetal morbidity included the presence of one of the following: fractures, neurological damage such as palsies, and Apgar scores of <5 at 5 minutes. Maternal morbidity refers to the presence of uterine rupture, postpartum hemorrhage, and fourth-degree lacerations of the vagina.

The Fisher exact test and χ^2 with the Yates correction were used for statistical analysis.

Results

The risk factors for shoulder dystocia in both groups are described in Table 1. There was no significant difference in average weight or percentage of macrosomia between the two groups. Diabetes was present in only one patient in group 2 in a case with induction at 38 weeks and delivery of a 3880 gm infant. There was no significant difference in the risk factors related to macrosomia between the two groups. Midforceps delivery and a prolonged second stage were more common in group 1 compared to group 2; however, the difference between the two groups was not statistically significant. Although the combination of these two risk factors was 3.5 times more common in group 1 (21%) versus group 2 (6%), this difference did not prove to be statistically significant.

The neonatal and maternal complications are given in Table II. The morbidity associated with true shoul-

Table I. Risk factors in true and coded shoulder dystocia

Risk factor	True shoulder dystocia (n = 24)*		Coded shoulder dystocia (n = 67)†	
	n	%	n	%
Macrosomia				
Multiparity	15	63	38	57
Previous macrosomia	2	8	11	16
Obesity	4	17	6	9
Diabetes	0	0	1	1
Postterm	2	8	9	13
Prolonged second stage	6	25	8	12
Midforceps delivery	12	50	20	30
Prolonged second stage and midforceps delivery	5	21	4	6

*Average weight ± SD = 4069 ± 277 gm.
†Average weight ± SD = 3979 ± 472 gm.

der dystocia (group 1) was 42% (10 of 24 cases) as compared to 1.5% (one of 67 cases) in group 2 ($p < 0.005$). Morbidity in group 1 consisted of six cases of Erb's palsy, five fractured clavicles, and one respiratory arrest that was successfully recuscitated. In two cases the neonate had sustained more than one type of injury. In group 2 there was only one neonatal complication of a low Apgar score at 5 minutes, which resolved by 10 minutes. There was only one case of maternal morbidity, a fourth-degree tear that occurred in group 1.

The relationship between the maneuvers performed and the fetal outcome is given in Table III. All orthopedic and neurological damage was associated with a combination of traction and fundal pressure. Delivery of the posterior shoulder and the corkscrew maneuvers were associated with complications in only one case, in which a series of maneuvers were attempted which resulted in the case of respiratory arrest mentioned above. The child was successfully resuscitated, and follow-up of more than a year failed to reveal any developmental abnormalities.

Comment

Because of the retrospective nature of this paper, there is room for error. Those cases designated as coded shoulder dystocia may in fact be true shoulder dystocia if maneuvers were not appropriately documented. However, rigorous comparison between doctors' and nurses' notes revealed a high degree of consistency which we feel should minimize this source of error.

Acker et al.[6] have determined protraction and arrest disorders to be significantly associated with shoulder dystocia. Likewise, Benedetti and Gabbe[3] have identified prolonged second stage combined with midforceps delivery as an intrapartum risk factor. Our study found

Table II. Neonatal and maternal complications of shoulder dystocia

Complications	True shoulder dystocia (n = 24)		Coded shoulder dystocia (n = 67)	
	n	%	n	%
Neonatal				
Low 5 min Apgar score	1	4	1	1.5
Neurological	6	25	0	0
Orthopedic	5	21	0	0
Maternal				
Fourth-degree tear	0	0	1	1.5

Table III. Maneuvers for shoulder dystocia and neonatal complications

Maneuver	No. of patients	Complications	
		n	%
Fundal pressure	13	10	77
Delivery of posterior shoulder	5	1*	20
Corkscrew	6	1*	17
Suprapubic	1	1*	

*Only one patient underwent a series of maneuvers (suprapubic, corkscrew, delivery of posterior shoulder) which resulted in fetal hypoxia.

the incidence of combined prolonged second stage with midforceps delivery to be considerably more common in true shoulder dystocia (ratio, 3.5:1). Although the Fisher exact test revealed a p value of 0.0508, the lack of significance with χ^2 with the Yates correction may be a reflection of the small numbers used for analysis.

Macrosomia is a well-documented risk factor for shoulder dystocia.[8] There was only one instance of diabetes in group 2, and it was not associated with macrosomia. This may reflect the practice of diabetic patients being delivered before 40 weeks, often by a cesarean delivery, and possibly a better control of diabetes in pregnancy. Macrosomia was not more common in the true shoulder dystocia group, which suggests that body configuration in macrosomia may be more important than macrosomia per se. This concept was suggested by Modanlou et al.,[5] who performed anthropometric studies post partum which revealed that macrosomic neonates with shoulder dystocia had a greater shoulder-head and chest-head disproportion regardless of birth weight. Their findings paralleled ultrasound studies in diabetic mothers in which a macrosomia index was calculated by subtracting biparietal diameter from chest diameter. Elliot et al.[9] suggested that an index >1.4 cm suggests shoulder dystocia. Such measurements may be indicated before labor if ultrasonographic estimated fetal weight is >4000 gm.

The morbidity rate of 42% was high but not incon-

sistent with other reports.[2, 3] The corkscrew maneuver and delivery of the posterior shoulder were associated with good fetal and maternal outcome. It is interesting that there was no documentation of hip flexion (McRoberts maneuver), which is reported to be simple and effective.[10] Fundal pressure in combination with traction was associated with neurological and orthopedic complications. The above findings would not be unexpected in light of the mechanism of fundal pressure which further impacts the anterior shoulder into the pubic bone, increases the risk of brachial plexus injury, and necessitates increased traction to accomplish the delivery. Furthermore, the use of this maneuver delays the implementation of more effective techniques.

Shoulder dystocia is a rare complication of labor that most obstetricians encounter infrequently. Management of shoulder dystocia is therefore often based on cumulative experience. A high index of suspicion should be maintained in the presence of certain risk factors. The present study also suggests that maneuvers such as the corkscrew maneuver or delivery of the posterior shoulder, which are mechanically logical, are safer than use of traction combined with fundal pressure, which only serves to compound the existing problem.

Cervical ripening and labor induction with prostaglandin E_2 gel: A placebo-controlled study

Paul Bernstein, M.D., Nicholas Leyland, M.D., Paul Gurland, M.D., and Douglas Gare, M.D.

Toronto, Ontario, Canada

A randomized double-blind, placebo-controlled study was undertaken to evaluate the effect of a single intracervical application of prostaglandin E_2 gel on the ripening of the cervix and on the subsequent induction of labor with oxytocin in patients with low Bishop scores (≤ 4). Compared to controls receiving gel only, the group receiving prostaglandin E_2 gel had significant increases in their cervical Bishop scores, shorter induction-to-delivery intervals, shorter time requiring use of oxytocin, and more successful labor induction without oxytocin. Systemic side effects were minimal and fetal outcomes were comparable, as were the routes of delivery. (Am J Obstet Gynecol 1987;156:336-40.)

Key words: Induction of labor, cervical ripening, prostaglandin E_2

Spontaneous labor and vaginal delivery in uncomplicated parturition follow a cascade of synchronous events that include the softening and effacement of the cervix. If this "ripening" of the cervix fails to occur, it may be accurately predicted that attempts at induction will be prolonged if not completely unsuccessful.[1]

Various complications of pregnancy may necessitate

delivery before the cervix has undergone the ripening process. This may serve to impede attempts at induction and predispose patients to increased fetal and maternal morbidity.

A number of clinical trials have supported the efficacy of prostaglandin E_2 in facilitating subsequent attempts of the induction of labor.[2,3] Of all the reported routes of prostaglandin administration, the direct application of the agent into the cervix appears to be the most advantageous in terms of increased efficacy and diminished side effects.[4]

The objective of this study was to determine, in comparison to placebo application, the effect of a single intracervical dose of prostaglandin E_2 gel on cervical ripening and the subsequent induction of labor with oxytocin.

Material and methods

Women who presented with medical and/or obstetric indications for the induction of labor were enrolled in the study from the Mount Sinai and Toronto General Hospitals. Ultimately 107 women were included in the analysis.

Admission criteria included written informed consent before entry into the trial, a gestational age of ≥36 weeks, Bishop score of ≤4, and parity of ≤3.

Exclusion criteria included known hypersensitivity to prostaglandins, any previous attempt at the induction of labor or cervical ripening, previous uterine surgery, suspected or clinically evident fetal compromise, vaginal bleeding, ruptured membranes, and fetal death in utero.

Patients were then randomized in a double-blind fashion to the prostaglandin E_2 group (n = 52) or the control group receiving the placebo (n = 55). On admission to the hospital, the patients were observed for 30 minutes during which time a nonstress test was performed, maternal vital signs were monitored, and the initial laboratory tests were obtained. These included a complete blood count and differential, renal, and liver function tests and urinalysis.

If no abnormalities were detected and the inclusion criteria were met, the initial Bishop score was assigned (Table I). After this, under direct cervical visualization, either 0.5 mg of prostaglandin E_2 in 2.5 ml of gel or a placebo administration of 2.5 ml of gel only was injected by means of a prepared syringe and a sterile 2.5 mm Portex catheter into the cervical canal to the level of the internal os.

The patients then remained in the delivery suite where cardiotocographic monitoring was performed continuously for 1 hour and intermittently thereafter. Maternal vital signs were recorded every 15 minutes for 1 hour, every hour for 3 hours, and every 4 hours thereafter.

Patients who went into labor were managed and monitored by their attending obstetrician as deemed appropriate. Labor was defined as the onset of regular uterine contractions resulting in the effacement and dilatation of the cervix to ≥3 cm.

If labor did not ensue by reassessment at 12 hours (t_{12}), a second Bishop score was assigned by the same observer and oxytocin induction was commenced with a use of 10 U of oxytocin per liter of ⅔:⅓ solution beginning at a rate of 2 mu/min, doubling the concentration every 15 to 20 minutes as necessary. If labor commenced, each case was managed individually by the patient's obstetrician. In those cases where no active labor was detected after 12 hours of oxytocin administration, the decision to continue or to cease induction attempts was made by the attending physician. Patients were followed as to outcome and number of induction attempts, and the results are given in the following section.

Statistical analysis consisted of Wilcoxon, Mann, and Whitney rank sum analysis, and in addition, an analysis of variance technique was used to assess the influence parity on the outcome parameters.

Table I. Cervical scoring chart

	Score		
	0	*1*	*2*
Dilatation (cm)	0	1-2	3-4
Effacement (%)	0-30	40-50	60-70
Station	−3	−2	−1/0
Consistency	Firm	Medium	Soft
Position of cervix	Posterior	Middle	Anterior

Table II. Comparison of study groups

	Prostaglandin E_2 group (n = 52)	*Placebo group (n = 55)*
Age (yr)	29.3 ± 5.7	29.7 ± 4.5
Weight (kg)	75.7 ± 12.7	77.5 ± 15.6
Gestational age (wk)	40.95 ± 1.6	41.09 ± 1.39
Gravidity	1.76 ± 1.0	1.76 ± .90
Mean arterial pressure (mm Hg)	92.0 ± 11.5	89.25 ± 10.0
Parity	0.35 ± 0.59	0.41 ± 0.79

Results

Table II illustrates that the prostaglandin E_2 and placebo groups were comparable in terms of age, weight, gestational age, gravidity, mean arterial pressure, and initial Bishop scores (t_0).

A comparison of the indications for induction of labor (Table III) reveals the two groups to be similar with the most frequent induction being postdates.

Table IV summarizes the outcomes of the various phases of the study. As can be seen, the two groups began the study with similar Bishop scores (t_0); however, the scores 12 hours after cervical application (t_{12})

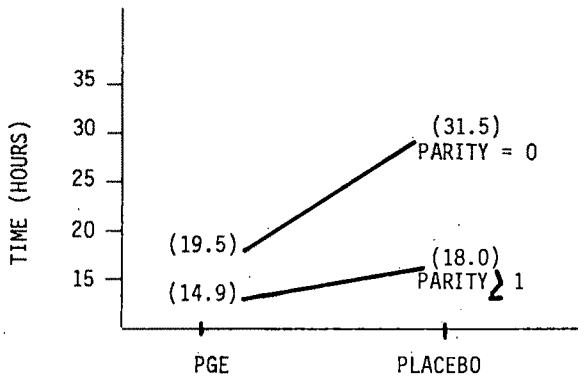

Fig. 1. Time (in hours) from t_0 to delivery. Effect of parity is illustrated. Both multiparous and primiparous women required significantly less time after prostaglandin E_2 *(PGE_2)* administration than after placebo administration, although multiparous women demonstrated a more pronounced effect.

Table III. Reasons for induction

	Prostaglandin E_2 group	*Placebo group*
Postdates	32	40
Preeclampsia/hypertension	9	6
Renal disease	1	0
Urticaria	0	1

Macrosomia	1	0
Diabetes	0	3
Repeat false labor	1	0
Sample size	52	55

reveal a statistically significant increase in the prostaglandin E_2 scores ($p < 0.005$). In addition, a comparison of the net changes in Bishop scores (t_{12}-t_0) is also significant ($p < 0.0007$).

In a comparison of all patients, the time in hours from t_0 to complete dilatation and to delivery were both significant ($p < 0.0001$ and $p < 0.0002$, respectively).

Of those patients requiring oxytocin for induction (prostaglandin E_2 group, n = 22; placebo group n = 45), the time from induction to delivery was significantly lower in the prostaglandin E_2 group ($p < 0.05$) (Fig. 1).

The time from amniotomy to delivery and the maximum dose of oxytocin did not achieve statistical significance. The placebo group received oxytocin for purposes of induction for a greater length of time ($p < 0.03$).

Of the 52 patients receiving prostaglandin E_2 gel, 32 (60%) achieved labor; of these, 17 (33%) were delivered without requiring oxytocin. In the control group eight of 55 (15%) went into labor and six (11%) were delivered without receiving oxytocin.

Table V uses analysis of variance to clarify the role of parity on the outcome parameters found to be significant. For the parameters of time t_0 to delivery and t_0 to full dilatation, both parity and group effects (prostaglandin E_2 or placebo) are significant. In other words, the gel is effective in nulliparous and multiparous women, but it appears to have a greater effect in the former. There is no interaction between the group or parity effect.

For the subpopulation of patients which excludes those in whom labor began before oxytocin induction, no significant parity or group effect or interaction is demonstrated. This would indicate that for those patients not achieving labor within 12 hours of gel insertion, the effects on the subsequent induction of labor are less significant (Table VI).

There were no significant differences in mode of delivery (Table VII). The cesarean section rate in the prostaglandin E_2 group was 30.7% compared to 24% in the placebo group. This was not statistically significant. The indications for cesarean section are listed in Table VIII.

Laboratory parameters before and after the study did not change in either patient groups significantly. Maternal peripartum morbidity was minimal in the two groups. No significant side effects resulting from prostaglandin administration were observed. Previous series have reported systemic side effects such as fever, nausea, diarrhea, and uterine hypertonus. There were two cases of increased uterine activity in the period immediately after gel insertion. This resulted in variable decelerations in one case that responded to repositioning the patient, oxygen, and intravenous fluid bolus. The fetal heart rate tracing became normal. In the second case there was persistent fetal tachycardia and fetal heart rate decelerations. Delivery by cesarean section was accomplished 2 hours after gel insertion on the decision of the attending obstetrician. Both infants had Apgar scores of 8 and 9 at birth.

Fetal outcomes with regard to weight and Apgar scores at 1 and 5 minutes, respectively, were comparable between the two groups (Table IX).

In the group receiving placebo (gel only), three patients had evidence of tetanic contractions at the onset of oxytocin the next morning. In all three the uterus was allowed to relax and the induction resumed after a short time interval. Thus it is apparent that in both modes of induction the presence of hypertonic uterine activity may pose a problem.

Comment

On review of the literature, several studies have been performed evaluating the efficacy of prostaglandin E_2 in facilitating or initiating labor.[5, 6] Various routes

of administration (intravaginal, intracervical), variable forms of administration (tablets, gels), and varying dosages and dosage schedules have been used.[7, 8]

As stated in the introduction, our goal is to determine a safe and reliable method of ensuring that an indicated induction proceeds smoothly for both mother and fetus. Widespread acceptance of prostaglandin E_2 has met with some resistance because of unpredictable absorption and concerns regarding systemic toxicity and uterine hypertonia.

In more recent reports it would appear that lower doses of prostaglandin E_2, such as the 0.5 mg used in the study, can be both safe and efficacious. Clinical research in this area has been hampered by the lack of a stable preparation of uniform dose. The product used in the study was prostaglandin E_2, 0.5 mg, stabilized in a viscous methylcellulose gel supplied by the Upjohn Company of Canada.

In this study, as in previous reports,[2, 3] a single-dose regimen given in a double-blind, placebo-controlled fashion facilitated cervical ripening, and in addition, by itself induced labor in a significant proportion of patients. For those patients not achieving labor, the subsequent induction of labor was facilitated by the preinduction prostaglandin application. The drug appears to be free of major side effects for mother or fetus. It

must be stressed, however, that this trial was carried out under strict surveillance techniques.

Prostaglandin E_2 gel does induce uterine contractility and may occasionally result in uterine hypertonia. Because the conditions that most frequently necessitate induction, that is, postdates, hypertensive disorders of pregnancy, intrauterine growth retardation, etc., may be associated with placental insufficiency, the "ripening" period must include careful fetal monitoring throughout the entire latent period but especially in the first 1 to 2 hours. It is therefore our opinion that this drug can be safely used in any setting in which a cesarean section can be accomplished quickly if indicated.

In some studies reviewed there is the suggestion that use of an effective ripening agent might reduce the overall incidence of cesarean section.[9] In this study both groups had statistically comparable rates of cesarean section; however, it is of interest that few if any were due to "failed induction," so one might conclude that any approaches previously including "failed induction" as an indication for cesarean section will definitely benefit from the use of prostaglandin E_2 gel.

Some questions, of course, remain unanswered. It is still not clear as to what is the optimal preinduction period after administration of a single dose of prostaglandin E_2 gel (4, 8, or 12 hours). Additionally, the potential benefit of supplementary doses for those persistently unfavorable cervices needs to be evaluated. Indeed studies are now being carried out to assess low-dose repetitive cervical applications of prostaglandin E_2 gel.

In summary, a single low-dose intracervical application of prostaglandin E_2 gel proved to be a safe and reliable aid in dealing with indicated but potentially difficult inductions. The product has the advantages of being uniformly prepared, accurate in dosage, stable, easy to apply, and associated with minimal side effects for mother or fetus.

We wish to thank the Upjohn Company of Canada for their support of this project and also to thank the case room nurses whose efforts made the study possible.

Clinical utility of multiple-dose administration of prostaglandin E_2 gel

Thomas Mainprize, M.D., Carl Nimrod, M.B., Gail Dodd, R.N., and David Persaud, M.Sc.
Calgary, Alberta, Canada

An open-label study was undertaken to assess the clinical impact of multiple doses of intracervical prostaglandin E_2 (0.5 mg) gel administered at 6-hour intervals. Fifty women with low Bishop scores requiring induction of labor were recruited. The prestudy mean Bishop score was 2.3 ± 1.1 and changed significantly with one ($p < 0.001$), two ($p < 0.001$), and three ($p < 0.002$) doses. The mean gestational age of patients receiving three doses was significantly less than that of patients receiving one dose, (38.5 versus 40.1 weeks, $p < 0.005$). Prostaglandin E_2 gel induced labor in 56% of patients, but 14% required subsequent oxytocin (Syntocinon) augmentation. Cesarean section was performed in 6% of patients. No deleterious fetal, neonatal, or maternal effects occurred. (Am J Obstet Gynecol 1987;156:341-3.)

Key words: Obstetrics, prostaglandin E_2, induction of labor

Prostaglandins are effective in ripening the unfavorable cervix and inducing labor.[1-3] The low incidence of side effects, especially gastrointestinal, has made the intravaginal and intracervical routes of administration popular.[4, 5]

Ripeness of the cervix influences the success of induction, thus the patient with an unfavorable cervix represents a greater challenge when induction is deemed necessary.[6] In a previous study,[5] we demonstrated that single-dose intracervical prostaglandin E_2 (PGE_2) was efficacious in changing the Bishop score and inducing labor in a double-blind placebo-controlled situation. In that study, however, 40% of the patients receiving PGE_2 did not go into labor and a significant proportion of these did not achieve cervical ripeness during the 12-hour observation period. It seemed reasonable, therefore, to consider multiple gel applications in situations in which a satisfactory result was not achieved with a single dose and, from a practical standpoint, reduce the interval of gel application from 12 to 6 hours.

This study was therefore designed to assess the clinical utility and patient safety of a protocol that allowed the administration of multiple doses of intracervical PGE_2 in women with low Bishop scores requiring induction.

Material and methods

This study was an open-label design involving multiple administration of PGE_2 gel to a maximum of three doses at 6-hour intervals. The study population of 50 patients was drawn from patients admitted by their attending physician for induction of labor at Foothills Provincial General Hospital. Patients were included if they had gestation ages of ≥36 weeks, a parity of 0 to 3, a modified Bishop score of ≤4, and an expected vaginal delivery of a healthy newborn infant. Patients who had contraindications to uterine stimulation were excluded.

Bishop score was determined and informed consent obtained. Laboratory evaluation, including complete blood count and urinalysis, was made before initial administration and repeated within 48 to 72 hours after the last dose.

After a 30-minute evaluation period, 0.5 mg of PGE_2 in 2.5 ml of tri-acetin gel was administered into the cervical canal via a nylon catheter. Direct visualization of the cervix obtained by use of a speculum enabled the investigator to reach the internal os and withdraw the catheter slightly. Allowances were made for the catheter volume by an overfill in the syringe. The catheter was removed directly after administration and the

6-hour observation period was initiated. Detailed assessment of contractions and electronic monitoring of maternal and fetal health parameters were used throughout the study period.

Bishop score was determined 6 hours after initial administration by the same investigator if the patient was not in labor. For the purpose of this study, labor induction by gel was defined as the initiation of regular contractions with a dilation of the cervix of ≥3 cm. If the reassessed Bishop score was ≤4, a second dose of gel was given and a second 6-hour observation period initiated. The same procedure was performed at the end of the second 6 hours, and a 12-hour observation period followed the third dose. Subsequent labor induction with continuous intravenous oxytocin was commenced if the patient was not in labor either 12 hours after the third dose (24 hours after the initial dose) or after a Bishop score of >4 was achieved at the end of the observation period. Oxytocin was continued until delivery or for 12 hours, at which time the attending physician decided on further management. Augmentation of labor was determined by the investigator and amniotomy was withheld until labor was established.

Evaluation of labor, delivery, neonatal outcomes, and side effects were documented. Data were analyzed by χ^2 analysis.

Results

The indications for induction are summarized in Table I. Eighty percent of the study group fell into the categories of postmaturity, pregnancy-induced hypertension, and intrauterine growth retardation.

Tables II and III demonstrate data with respect to maternal age, gestational age, prestudy Bishop scores, change in Bishop scores, labor characteristics, and delivery outcomes for primiparous and multiparous women. Results showed the two groups to be comparable in all aspects and indicate that in situations with poor Bishop scores parity does not appear to affect the number of doses of gel required.

The mean change in Bishop scores from 0 to 6 hours was 3.4 ± 1.7 for primiparous women and 3.4 ± 2.3 for multiparous women, showing no statistically significant difference. There appeared to be a trend toward a higher mean change in Bishop score from 6 to 12

hours in the primiparous women; however, a statistically significant difference was not achieved. Comparison of the prestudy Bishop score with 6- and 12-hour evaluations is shown in Table IV. A statistically significant difference was achieved and illustrates the efficacy of intracervical PGE_2 gel in affecting Bishop score.

Of the study population, 28 (56%) of the patients went into spontaneous labor, and seven of them required oxytocin augmentation. Surgical amniotomy was performed in 25 patients after labor was established.

Delivery outcomes showed that 47 (94%) of the patients achieved vaginal delivery. Three cesarean sections were performed because of cord proplapse, fetal distress, and failure to progress. The patient with failure to progress had a prestudy Bishop score of 0, which did not change despite three doses of PGE_2 gel.

Newborn Apgar scores were unaffected by the number of doses received, and 49 (98%) of the newborn infants were discharged after an uncomplicated hospital course. One neonate delivered by cesarean section because of cord prolapse was admitted to the neonatal intensive care unit for evaluation with a diagnosis of diaphragmatic hernia.

Postpartum hemorrhage occurred in three patients. Estimated loss was >500 ml; however, all cases were managed conservatively without the need for transfusion.

Comment

Data obtained in this study demonstrate the effectiveness of multiple-dose administration of PGE_2 gel at 6-hour intervals in changing Bishop scores and subsequent induction of labor irrespective of parity.

A higher mean gestational age in patients requiring one dose of gel might possibly contribute to a higher prestudy Bishop score in these patients and further indicate that Bishop score appears to be the more important variable in successful induction.

Forty-seven (94%) of 50 patients achieved vaginal delivery. A 6% cesarean section rate compares favorably with lower rates seen after prostaglandin priming compared with placebo.[7]

More rapid absorption of PGE_2 from cellulose gel rather than from tablets was demonstrated by Gordon-Wright.[8] An increased frequency of side effects might be anticipated with gel, but this did not occur in our study. Indeed, no adverse fetal or maternal effects could be attributed to PGE_2. Two cases of fetal distress were not associated with hypertonic uterine contractions; cord prolapse was diagnosed in one case. Nausea, when it occurred, was related to the use of narcotics for analgesia. The 6-hour interval between doses may reduce potential side effects from drug accumulation; however, this needs further study.

The incorporation of a protocol allowing repeated application of PGE_2 gel at 6-hour intervals in patients with an unfavorable cervix was useful in achieving a successful induction of labor and a low cesarean section rate and was unaffected by the parity of the patient. The absence of side effects in this study confirmed the safety of this regimen.

Immunosuppressor factor(s) produced by decidua-associated suppressor cells: A proposed mechanism for fetal allograft survival

Salim Daya, M.B., Ch.B.,* Kenneth L. Rosenthal, Ph.D., and David A. Clark, M.D., Ph.D.**

Hamilton, Ontario, Canada

Mechanisms that explain failure of rejection of the antigenic fetus by the mother appear to lie at the fetomaternal interface. Successful pregnancies have been correlated with the presence of decidua-associated suppressor cells. Supernatants from these cells were tested for their ability to suppress the proliferation of interleukin 2–dependent cells and were also subjected to high-performance liquid chromatography. Decidual supernatant was found to have peak suppressive activity at two molecular weights (43,000 and 21,000 daltons). The activity of decidual supernatant was directed specifically at interleukin 2–dependent cells and interfered with interleukin 2 action. The importance of this mechanism in graft rejection is well known. Decidual supernatant may thus prevent fetal allograft rejection by preventing the maternal cytotoxic effectors from receiving the interleukin 2–dependent help that they need to proliferate and remain actively cytolytic. (Am J Obstet Gynecol 1987;156:344-50.)

Key words: Decidua, fetal allograft survival, interleukin 2

The mammalian fetus may be viewed as a type of allograft that is capable of survival in an immunologically hostile host. The fetus itself bears transplantation antigens against which the maternal immune system can react. Priming against fetal alloantigens in vivo results in the formation of antipaternal cytotoxic reactivity which has no effect on fetal health or survival.[1] Alloimmunization in several strain combinations of female mice against paternal antigens does not result in antibody formation despite the presence of major histocompatibility complex differences between the mother and fetus.[1] Thus systemic immunosuppression by allospecific T suppressor cells or by "blocking" antibodies does not appear to be necessary for survival of the fetal allograft.

In contrast, allografts placed at the choriodecidual junction experience prolonged survival despite the presence of class I major histocompatibility complex antigens on some fetal trophoblast populations which also resist lysis by natural killer cells and cytotoxic T lymphocytes.[2] Fetal rejection, however, is associated with an infiltrate of maternal cytotoxic cells, which appear to first pass through or between the trophoblast without causing lysis of the latter.[3] Such rejection has also been associated with a local deficiency in the decidua of nonspecific suppressor cells.[3, 4] These suppressor cells appear to be activated or recruited by trophoblast cells. The immunologic success or failure of the fetal allograft, therefore, appears to be determined largely by events at the fetomaternal interface.

Two types of maternal suppressor cells have been isolated from the human uterine lining.[4] These cells suppress the ability of maternal T cells to proliferate in response to concanavalin A. A large, probably hormone-dependent suppressor cell has been isolated from the endometrium of normal menstrual cycles. The suppressive activity of this cell is seen only in the luteal phase and is absent in the proliferative phase. Maximal activity appears to be present at a time when implantation would normally occur. A second, smaller, and probably trophoblast-dependent suppressor cell has been isolated from the decidua of successful pregnancies. Its activity is present even in the first pregnancy, and it is seen to gradually decline as term approaches.

The mechanism of suppression by these human suppressor cells has not been determined. In this article we show that decidua-associated suppressor cells elaborate soluble factors that have immunosuppressive properties through their ability to block interleukin 2 action. The importance of this mechanism is discussed,

since it is known that interleukin 2 is a key molecule involved in the activation and proliferation of cytotoxic T lymphocytes that are necessary to mediate allograft rejection.

Material and methods

Animals. Mice of C3H/HeJ and DBA/2 strains were purchased from the Jackson Laboratory, Bar Harbour, Maine. Four or five were housed per cage and allowed water and food ad libitum. Sprague-Dawley rats were purchased from Charles River Laboratories, St. Constant, Quebec.

Cell preparation. All cells were resuspended in α–minimal essential medium supplemented so as to contain 10% fetal bovine serum, 100 μg/ml of penicillin, 100 μg/ml of streptomycin, 20 mmol/L of Hepes, sodium bicarbonate and 2.92 mg/100 ml of L-glutamine. Preparation included the following steps: (1) Peripheral blood lymphocytes were separated from venous blood by density centrifugation with use of Isopaque-Ficoll as previously described.[4] (2) Decidual lymphocytes were separated from decidua obtained by uterine curettage after elective abortion in the late first trimester. The lymphoid cells were separated by density centrifugation after single cell suspensions of the material were made as previously described.[4] (3) Endometrial lymphocytes were obtained by dilatation and curettage in the luteal phase from women with normal menstrual cycles undergoing infertility assessment. The lymphocytes were prepared in a similar way to decidual lymphocytes. (4) Peripheral lymph node lymphocytes were obtained from 6- to 8-week-old virgin C3H/HeJ female mice. (5) P815 (H-2d) mastocytoma cells were serially propagated in ascites in DBA/2 male mice. (6) YAC-1 lymphoma cells were cultured in vitro in RPMI supplemented to contain 10% fetal calf serum, 1% L-glutamine, 1% penicillin and streptomycin, 1% Hepes, and 1% sodium bicarbonate. (7) OW-7 human ovarian carcinoma cells (provided by Dr. R. N. Buick, Ontario Cancer Institute, Toronto, Canada) were grown in vitro in RPMI and disloged with use of trypsin before being resuspended in α-minimal essential medium.

Generation of supernatants. Preparations of 2×10^6 decidual lymphocytes and endometrial lymphocytes were each incubated in 1 ml of α-minimal essential medium for 48 hours at 37° C in 6% to 7% carbon dioxide. The cell-free supernatant was removed and stored at 4° C.

Purification of suppressor factor from crude decidual supernatant. Decidual supernatant was purified by high-performance liquid chromatography. A TSK gel G3000SW column (Toyo Soda USA Inc., Atlanta) that had been preequilibrated with Tris (0.01 mol/L) in sodium chloride buffer (0.10 mol/L) at pH 7.0 was used.

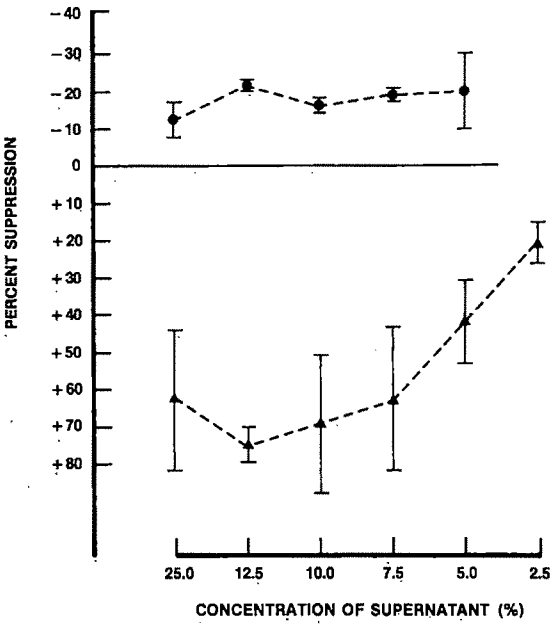

Fig. 1. Effect of endometrial and decidual supernatants on lymphocyte proliferation. Means ± SEM of three experiments showing the effect of various concentrations of endometrial supernatant (●) and decidual supernatant (▲) on concanavalin A–induced proliferation of human peripheral blood lymphocytes.

Fractions were eluted at a flow rate of 1 ml/min at room temperature. Each fraction was sterilized by filtration (Millex-GV 0.22 μm filter unit, Millipore Corporation, Bedford, Massachusetts) and then supplemented with fetal bovine serum to a final concentration of 10%. The column was calibrated with use of a variety of molecular weight markers, namely, β-amylase, alcohol dehydrogenase, bovine serum albumin, carbonic anhydrase, and ribonuclease.

Toxicity tests. Decidual supernatant was tested for toxic effect on lymphocytes by a comparison of the viability in 0.4% trypan blue of the cells cultured with use of decidual supernatant with the viability by means of medium alone.

Interleukin 2 responses. Interleukin 2 was prepared by concanavalin A stimulation of rat spleen cells with use of a standard method. Stated briefly, rat spleen cells at a density of 5×10^6 per milliliter were cultured in RPMI containing 5 gm/ml of concanavalin A; 48 hours later the supernatant was harvested after centrifugation at 1000 × g for 20 minutes. Supernatants were then sterilized by filtration and stored at −20° C until used. These interleukin 2 cells containing supernatants were tested for their ability to induce proliferation of H-Y cells, a cloned mouse natural killer cell line. This cell line has been shown to be interleukin 2–dependent with use of purified lymphokines (unpublished results). Twofold dilutions of interleukin 2 samples (at a final

‡Not significantly different from incorporation in medium alone; $p > 0.05$.

concentration of 5%) were prepared, and 50 μl containing 1×10^4 H-Y cells was added to each well in 96-well, flat-bottomed microculture trays (Linbro, Flow Laboratories Inc., Mississauga, Ontario, Canada). At the beginning 100 μl of decidual supernatant was added to the interleukin 2 assay to test for its ability to block the interleukin 2–dependent proliferative response. Incubation was carried out at 37° C for 24 hours. The cells were then labeled with 1 mCi of tritiated thymidine (New England Nuclear, Boston) for 6 hours, harvested onto glass fiber strips, and processed for detection of radioactivity in a Beckman liquid scintillation counter.

Suppression assay. Peripheral blood lymphocytes, at a density of 1×10^5 cells per well were cultured in α-minimal essential medium and stimulated to proliferate with concanavalin A at a final concentration of 10 mg/ml. Suppressive activity of decidual supernatant (purified and crude) and crude endometrial lymphocyte supernatant were tested for their ability to suppress proliferation of the peripheral blood lymphocytes when compared with medium alone. The cells were cultured in 96-well, round-bottomed microculture trays for 48 hours followed by the addition of 1 mCi of tritiated thymidine. Incubation was carried out for a further 16 to 18 hours before harvest and detection of radioactivity. A similar assay was used for mouse peripheral lymph node lymphocytes. The tumor cell lines, however, were grown for the same duration but without the addition of concanavalin A. Time course experiments were also performed by use of peripheral blood lymphocytes and by varying the time when crude decidual supernatant was added to the cell cultures.

Statistical analysis. The degree of tritiated thymidine uptake in counts per minute (cpm) was used to determine suppression activity, which was calculated with use of the following formula:

$$\% \text{ Suppression} = \frac{(\text{cpm without supernatant} - \text{cpm with supernatant})}{(\text{cpm without supernatant})} \times 100$$

Results

Soluble suppressive activity. Fig. 1 shows the effect of supernatant from endometrial and decidual lymphocytes on mitogen-induced proliferation of human peripheral blood lymphocytes. The endometrial lymphocytes from the luteal phase of menstrual cycle are known to have a direct suppressive activity,[4] but the cells did not mediate suppression by producing a soluble suppressor factor (top of Fig. 1). In contrast, the supernatant from decidua-associated cells was highly suppressive even in very low concentrations (bottom of Fig. 1). This suggests that the suppressive activity produced by decidua-associated suppressor cells was mediated by elaboration of a potent soluble suppressor factor (or factors).

Mechanism of inhibition of proliferation. The possibility that suppression of peripheral blood lymphocytes proliferation by decidual supernatant might be the result of a nonspecific toxic effect was evaluated. Incubation of human lymphocytes with decidual supernatant for 24 hours at 37° C had no effect on viability (90.1% in medium versus 88.7% in decidual supernatant, $p > 0.05$). Decidual supernatant was also added during the final 18 hours of 3-day human lymphocyte cultures with concanavalin A when lymphoblasts were present. Blasts cultured in the presence of decidual supernatant had a viability of 75.4% whereas blasts grown in medium alone were 78.6% viable ($p > 0.05$). Thus the suppressive activity of decidual supernatant was not attributable to toxicity to cells during short-term (<24-hour) exposure. To determine whether toxicity occurred after a longer incubation period, decidual supernatant was included in 3-day cultures of three different non–interleukin 2–dependent cell lines (Table I). Proliferation was not inhibited, confirming that the suppressive activity of decidual supernatant was not due to a nonspecific toxic effect on the cell.

It is known that interleukin 2 induces activated cytotoxic T lymphocytes to proliferate, migrate, and carry out allograft rejection. The inhibition of lymphocyte proliferation by decidual supernatant could represent an interference with the generation or action of interleukin 2. To determine whether this occurred, decidual supernatant was added to cultures of three different interleukin 2–dependent cell lines (Table II). Significant suppression of proliferation occurred with all three cell lines, indicating that decidual supernatant inhibited interleukin 2–induced cell proliferation. Fig. 2 shows a direct dose effect of decidual supernatant,

†Values represent mean ± SEM from four replicates of a typical experiment.

demonstrating a marked reduction in H-Y cell proliferation with increasing concentrations of decidual supernatant.

Time course suppression by decidual supernatant. It is known that interleukin 2 is produced during the first 24 hours of culture and then binds to interleukin 2 receptors on activated lymphocytes. To determine whether decidual supernatant could antagonize the action of interleukin 2 *after* it had bound to receptors time course experiments were undertaken. Fig. 3 shows the effect of adding decidual supernatant to human lymphocyte cultures at a final concentration of 1:8 between 0 and 48 hours following initiation of concanavalin A stimulation. When decidual supernatant was added after 18 hours, there was no suppression. These data suggested that decidual supernatant acted on the cell or interleukin 2 before receptor interaction.

Size of suppressive molecules in decidual supernatant. To define more accurately the molecular species responsible for suppression by decidual supernatant, separation into different fractions was carried out by high-performance liquid chromatography. Fig. 4 shows that two major peaks of suppressive activity were obtained that corresponded to molecular weights of 43,000 and 21,000 daltons, respectively. There was also a smaller peak of suppressive activity corresponding to 60,000 daltons.

Comment

Successful pregnancies have been associated with the presence of suppressor cells in the uterine decidua.[3, 4] The mechanism of suppression by these cells in the human has not previously been determined. The data in this paper show that decidua-associated lymphocytes in early human pregnancy elaborate a soluble suppressor factor that acts by blocking the action of interleukin 2. This is clearly seen in cultures of H-Y cells which depend on interleukin 2 for proliferation and do not require the presence of an antigen. The soluble factor from decidua suppresses proliferation, suggesting that it interferes in some way with interleukin 2 action possibly by preventing interleukin 2 from binding to its receptor. The fact that the action of human decidual supernatant is directed specifically at interleukin 2–dependent cells is also shown by the observation of inhibition of mitogen-induced proliferation of both human lymphocytes and mouse peripheral lymph node cells. In contrast, the proliferation of three non–interleukin 2–dependent cell lines, including YAC-1 (a mouse lymphoma), P815 (a mouse mastocytoma), and OW-7 (a human ovarian carcinoma), was not inhibited.

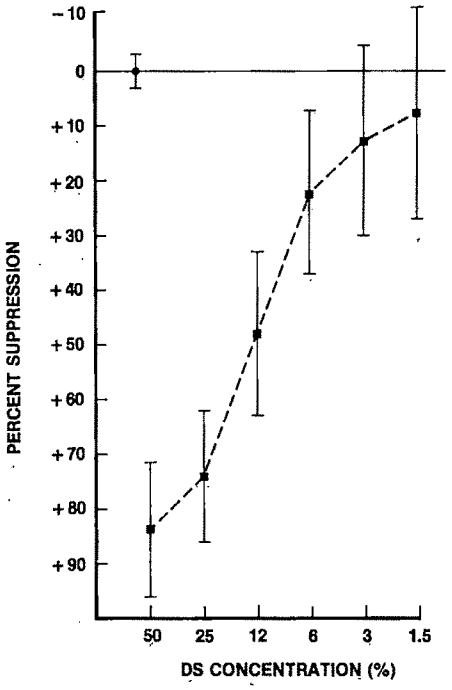

Fig. 2. Effect of decidual supernatant *(DS)* on interleukin 2–dependent cell proliferation. A 20% dilution of rat interleukin 2 was added to the interleukin 2–dependent H-Y cell line in the presence of decreasing concentrations of decidual supernatant (■) and in the presence of medium (●). Means ± SEM are shown.

The importance of interleukin 2 in graft rejection is well known. T helper cells become activated when presented with antigen and produce interleukin 2.[5] This augments the proliferation of alloantigen-specific cytotoxic T lymphocytes. It also activates and stimulates the proliferation of natural killer cells and a population of T cells (lymphokine-activated killer cells) that kill a variety of tumor cells that are resistant to specific cytotoxic T lymphocytes.[6-8] Thus a variety of cytotoxic effector cells can become activated through the effects of interleukin 2. This is necessary, since different types

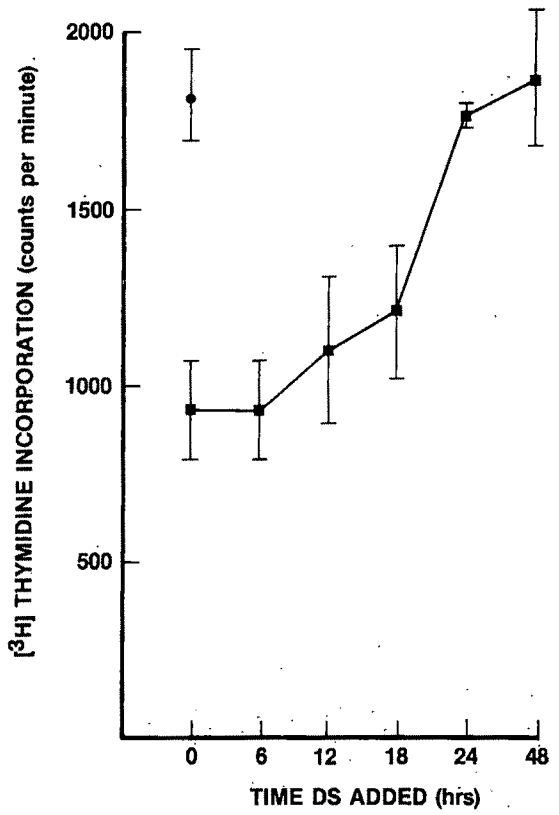

Fig. 3. Time course suppression by decidual supernatant. Decidual supernatant (■) at a final concentration of 12.5% was added to lymphocyte cultures at various times after initiation of concanavalin A stimulation. Medium (●) was used as control. Means ± SEM of three experiments are shown.

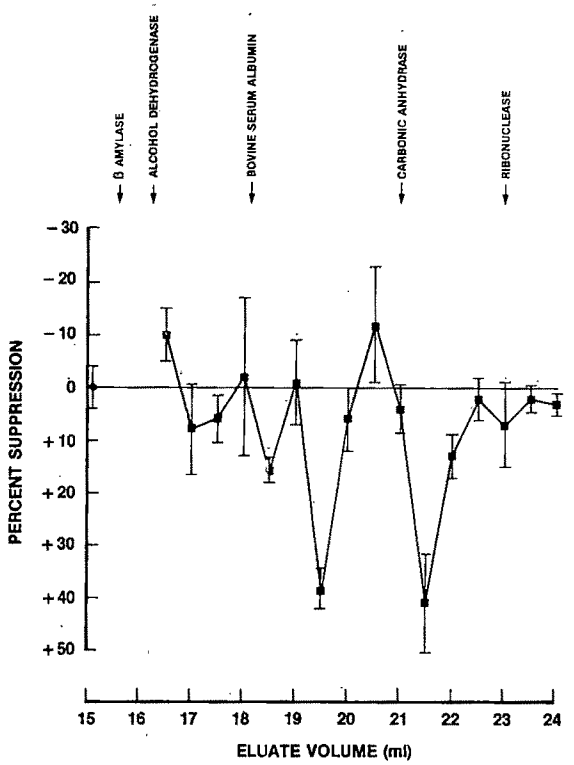

Fig. 4. Size of suppressive molecules in decidual supernatant. A 25% concentration of decidual supernatant was separated by high-performance liquid chromatography, and each fraction (■) was tested at a final concentration of 25% for suppression of concanavalin A–induced lymphocyte proliferation. Medium (●) was used as control. Means ± SEM are shown, as well as the molecular weight markers that were used for calibration.

of cells in a graft require different types of effector cells for their inactivation or destruction.[9] Antitumor effects of interleukin 2 have been determined by observing the rejection of nonimmune murine and human tumors into which it has been injected.[7, 10] Therefore it would seem that blocking the response to interleukin 2 could markedly affect the host's graft-destroying mechanisms. Decidual supernatant from decidua-associated suppressor cells may thus prevent fetal allograft rejection by preventing the maternal effectors from receiving the interleukin 2–dependent "help" that they need to proliferate and remain actively cytolytic. Since the motility of these effectors is interleukin 2–dependent, decidual supernatant may also block their migration into the fetus through the trophoblast.

There is some evidence to suggest that such suppressor activity may protect the antigen-bearing fetoplacental unit from adverse effects of maternal immunity. In situations of deficient suppressor cell activity in the uterus, the fetal allograft is highly susceptible to maternal antipaternal immunity. For example, in missed abortions in humans there is a deficiency of suppressor cell activity in the decidua.[4] Similarly a suppressor cell deficiency in decidua and in the lymph nodes draining the uterus correlates with the presence of spontaneous resorption of fetuses in allopregnant mice.[3] The inhibition of interleukin 2 responses by decidual supernatant would therefore be expected to protect fetuses from a variety of maternal effector mechanisms both in nonimmune animals and in women with transplantation immunity to paternal major histocompatibility complex antigens. Further studies are required to determine whether decidual supernatant can also inhibit some of these other effector cells such as natural killer cells, which kill embryonic cells and macrophages. This seems likely, since natural killer activity in the murine uterus decreases as pregnancy advances.[11]

The mechanism of activation of the decidua-associated suppressor cells is still under investigation. Decidual suppressor cells in the murine uterus are activated by trophoblast. Also recent studies of fractionated human luteal phase endometrial cells have shown that trophoblast membrane and soluble placental signals may be involved in this activation.[12] Therefore the fetus appears to be directly responsible for controlling its own survival in the mother. Failure to activate these

suppressor cells would then result in early pregnancy wastage.

The decidual supernatant factor was found to have a peak activity at two molecular weights, namely, 43,000 and 21,000 daltons, with a smaller peak of activity at 60,000 daltons. Whether these represent distinct molecules or are polymers or breakdown products is unclear. Decidual supernatant suppressor factor obtained from allopregnant mice (and which also blocks the response to interleukin 2) had a molecular weight of 80,000 to 100,000 daltons by sephacryl chromatography.[13] Recent studies with use of high-performance liquid chromatography methods have shown additional activities at 40,000 and 20,000 daltons (Clark et al., unpublished observations). Thus decidual supernatant appears to be similar in both the human and murine systems.

Other types of suppressor factors have been described in the literature. For example, Badet et al.[14] have obtained a 60,000 dalton factor from the decidua of syngeneically mated C3H mice as well as from deciduomas in which no trophoblast is present. Hardt et al.[15] described a T cell–derived factor in the serum of mice that inhibits the response to interleukin 2 and has a molecular weight of 50,000 daltons. Many tumor cells can also produce factors that suppress proliferation of T cells in vitro. These factors generally have molecular weights <50,000 daltons, and their mechanism of action has not yet been determined.

Other types of proteins produced by the human uterine lining have also been described in the literature. The functional properties of these proteins have not yet been determined. Progestogen-associated endometrial protein, a glycoprotein with a molecular weight of 47,000 daltons which can be reductively dissociated to two subunits with each having molecular weights of 27,000, has been isolated from human endometrium, and the amounts detected rise rapidly during early pregnancy.[16] Progestogen-associated endometrial protein appears to have a molecular weight similar to decidual supernatant, but it is not known whether it also has similar immunosuppressive properties. Other reports indicate that of the many secretory proteins of pregnancy endometrium, two appear more commonly during early pregnancy.[17] EP14 is a subunit with a molecular weight of 32,000 daltons that is associated with decidualized endometrium, and its rate of production increases during early pregnancy.[17] EP15, a subunit with a molecular weight of 28,000 daltons, is also produced by secretory endometrium during the menstrual cycle and during early pregnancy until 15 to 16 weeks' gestation after which it is no longer detectable. Again, no immunosuppressive activity has yet been detected with these proteins. Since skin grafts placed on deciduomas in parous immune mice are rejected whereas similar grafts at the choriodecidual junction are protected, trophoblast-dependent suppressor cells and their factors appear to be the major defense against rejection in vivo.[2]

It is rapidly becoming evident that fetal allograft survival against an active maternal immune system depends on a definable interaction of cells and immunomodulating factors at the fetomaternal interface. Development of monoclonal antibodies to the decidua-associated suppressor cell and its suppressor factor will provide more information about the intricate mechanism of this fetomaternal interaction. With this knowledge we may be able to develop a clearer understanding of the clinical problem of early embryo and pregnancy wastage and unexplained infertility. Ultimately we may be able to provide treatment for this chronic, frustrating, and distressing problem. One such treatment may be immunotherapy in women using allogeneic cells. This has been shown to boost decidual supernatant activity in mice, thereby preventing spontaneous abortion (Clark et al., unpublished observations).

We thank Rita Campbell for expert technical assistance.

Fetal foot length as a predictor of gestational age

Brian M. Mercer, M.D., Suzi Sklar, R.D.M.S., Anahita Shariatmadar, M.Sc., Martin S. Gillieson, M.D., and Mary E. D'Alton, M.D.

Ottawa, Ontario, Canada

Ultrasonographic measurement of fetal foot length is useful in the assessment of gestational age. Two hundred twenty-three postpartum and 224 ultrasonographic measurements were performed between 11 and 43 weeks' gestation; 207 postpartum and 160 ultrasonographic measurements met our requirements of secure dates and no physical anomaly or maternal disease. Mean foot length at each week of gestation compared favorably with Streeter's data, based on pathologic specimens, described in 1920. Comparison of curvilinear regression of foot length versus gestational age demonstrated a strong correlation with an R^2 value of 0.981; 95% confidence intervals at each week compared favorably with both biparietal diameter and femur length data. Fetal foot length is a reliable parameter for use in the assessment of gestational age and is particularly useful when other parameters do not accurately predict gestational age, for example, hydrocephalus, anencephaly, short limb dysplasia. (Am J Obstet Gynecol 1987;156:350-5.)

Key words: Pregnancy, ultrasound, gestational age, foot length

With the development of obstetrical ultrasound as an adjunct to antenatal assessment, many parameters[1-3] have been studied in attempts to assess fetal gestational age. In 1920 Streeter[4] reported a series of 576 pathologic specimens in which he correlated foot length to gestational age. Measurements were taken from the heel to the first or second toe. Many specimens were fixed with 10% formalin, which may cause tissue swelling. Usher and McLean[5] in 1969 gave similar results with postpartum data measuring from the heel to the longest toe of normal neonates. There are no studies that have reviewed foot length and growth in anomalous infants, multiple gestation, or pregnancies with maternal medical complications.

It was our intent to confirm Streeter's and Usher and McLean's data with postnatal foot length measurements. We planned to compare antenatal ultrasonographic measurements with our postpartum findings and develop a nomogram for ultrasonographic foot length as a predictor of gestational age. Finally, we hoped to demonstrate the usefulness of foot length measurement in special clinical cases such as multiple gestation, infants of diabetic mothers, the anencephalic fetus, and the fetus with short limb dysplasia.

Material and methods

A single observer performed 223 postpartum measurements of right heel to first toe within 4 days of delivery. Measurements were performed with a right-angled ruler calibrated in millimeters. Measurements were made without previous knowledge of gestational age. Inclusion requirements were normal pregnancy with neonatal weight appropriate to gestational age[5] and no physical anomaly. Repeat measurements were performed on 20 infants within 2 days of initial assessment.

Two hundred twenty-four ultrasonographic measurements were performed with use of the Siemens and General Electric real-time scanners with a 3.5 mHz lin-

ear-array transducer. Caliper measurements were documented with a Polaroid camera. Both plantar and longitudinal views of the foot were taken when possible (Fig. 1). Requirements for measurement were singleton gestation with secure dates and no identifiable anomaly or intercurrent medical illness. Ultrasonographic measurements were performed on 16 infants of diabetic mothers, eight pairs of twins, and two anencephalic fetuses. Ultrasound correlation to postnatal foot length was assessed with follow-up postpartum measurement of nine infants delivering within 3 days of ultrasonographic assessment.

Mathematical evaluation of the relationship between foot length and gestational age was performed with use of the linear regression model and curvilinear regression models based on exponential, logarithmic, power, and polynomial fits. The variation in foot length at each week of gestation was evaluated by a comparison of

deviation of observed foot length from predicted values based on the most accurate mathematical model. At each week of gestation 95% confidence intervals were calculated based on ±2 standard deviations from predicted foot length after statistical removal of systemic variation. This process was repeated for gestational age variation as a function of foot length.

Ultrasonographic foot length measurements of the twins, infants of diabetic mothers, and anencephalic fetuses were applied to the predictive curve to determine the reliability of foot length measurements in pregnancies with complicating factors.

Results

Two hundred seven of 223 neonates met our inclusion requirements. The mean foot length at each week of gestation was compared with Streeter's data (Table I). Comparison of 20 serial postpartum measurement pairs revealed similar means and standard deviations, with an average deviation of only 1.7% between measurements (Table II). Paired *t* test evaluation of the two data sets at a 95% confidence level revealed no significant differences, with a beta error of <0.1%.

Requirements for ultrasonographic assessment for the determination of the predictive curve were met by 196 patients; 36 patients did not have adequate documenting photographs and were excluded from further assessment. Measurement initially required up to 7 minutes to identify both poles of the foot. With experience, most feet could be reproducibly measured within 1 minute of scanning time. Difficulty was encountered in patients with oligohydramnios and footling breech presentations, since the foot image was indistinct when compared with the surrounding pelvic soft tissues. Comparison of plantar and longitudinal views revealed similar foot length measurements with insignificant measurement difference between ultrasonographers. Paired *t* test analysis was applied to nine pairs of postpartum measurements following initial ultrasonographic assessment. No significant difference was found at a 95% confidence level with a beta error of <1% (Table II, *B*).

Scatter plots of foot length versus gestational age and subsequently gestation age versus foot length were created (Fig. 2). As with postpartum measurements, mean ultrasonographic foot length at each week of gestation compared very closely to Streeter's data (Table I).

Curvilinear regression with use of the polynomial model demonstrated the best fit to the foot length data. These equations were obtained: (1) Foot length (mm) = $0.02728\ wk^2 + 4.4045\ wk - 36.74$, $R^2 = 0.981$. (2) Gestation (wk) = $7.745 \times 10^{-4}\ mm^2 + 0.3004\ mm + 9.397$, $R^2 = 0.977$.

Residual values from predicted measurements based on equations 1 and 2 were calculated. Systemic variation was noted to increase with gestational age and foot length, respectively (Fig. 3, *A*). This variation was removed by using a transformation in which the residual was expressed as a percentage of the predicted value[6] (Fig. 3, *B*). Standard deviations were calculated for the transformed data. The mean deviation ± 2 SD of the transformed residuals were −0.37 mm ± 11.0% for foot length versus gestational age and 0.07 weeks ± 7.97% for gestational age versus foot length.

Foot length measurements at a gestation of <12 weeks were significantly different from the predicted values with deviations of >30% at 10 and 11 weeks. These values were not included in further evaluation. Based on the regression equations and transformed residual plots, foot length growth and dating curves with 95% confidence interval were derived (Fig. 2, Table III).

Foot length measurements from the infants of diabetic mothers, twin pairs, and anencephalic fetuses all fell within the 95% confidence limits of the predictive curve (Fig. 4).

Case studies

Case 1. This patient presented at 30 weeks' gestation with a fundal height that was small for dates. Ultrasound assessment demonstrated a biparietal diameter of 78 mm, which was appropriate for gestational age. However, the femur length of 49 mm was appropriate to only 26 weeks' gestation. Foot length measurement of 60 mm confirmed biparietal diameter of gestational age estimation and suggested a presumptive diagnosis of short limb dysplasia. Serial measurements showed progressive delay of long bone growth. The diagnosis of osteogenesis imperfecta was confirmed at birth.

Case 2. The patient was scanned for estimation of gestational age. Biparietal diameter was appropriate for 20 weeks as was the foot length of 33 mm. However, humerus and femur lengths (10 mm) were appropriate

for only 13 weeks, suggesting a severe short limb dysplasia. Abortion revealed a fetus diagnosed as having osteogenesis imperfecta lethalis.

Comment

Mean foot length from both postpartum and ultrasound groups followed closely Streeter's predictive curve for foot length versus gestational age. There is minimal intraobserver and interobserver variation in both groups of observations.

The polynomial regression curves give the best fit to our ultrasound data with R^2 values of 0.98; 95% confidence intervals based on 2 SD from the predicted values (Table III) are ±1.6 and ±2.4 weeks at 20 and 30 weeks, respectively. These values compare favorably with both biparietal diameter and femur lengths at similar gestations (Table IV). Fetal foot length measurement is a reliable estimator of gestational age between 12 and 40 weeks in normal pregnancies as well as those complicated by diabetes, multiple gestation, anencephaly, and short limb dysplasia.

Ultrasonographic foot length measurement should be undertaken when other parameters do not accurately predict gestational age as well as when abnormality of long bone length or biparietal diameter is suspected. In cases of preterm labor, in which assessment of several growth parameters helps to better approximate gestational age more accurately, the addition of fetal foot length measurement may aid in crucial management decisions.

We respectfully acknowledge Ms. S. Gaudette, Mrs. J. Wotherspoon, and Ms. K. McAuliff for help in the preparation of this paper.

The effect of hydralazine on placental perfusion in the spontaneously hypertensive rat

Jeffrey Lipshitz, M.D., Robert A. Ahokas, Ph.D., and Samuel L. Reynolds, M.S.
Calgary, Alberta, Canada, and Memphis, Tennessee

Intravenous hydralazine was administered to 16 spontaneously hypertensive rats on day 21 of gestation. The radioactive labeled microsphere technique was used to assess the change in organ perfusion produced by the drug. Vascular resistance to most organs was decreased, except to the placentas, stomach, and cecum, where it increased by 43%, 104%, and 44%, respectively. Blood flow to the organs was redistributed, and although it was increased to the lungs, kidneys, liver, and adrenals, it was significantly reduced to the spleen, stomach, placentas, cecum, large intestine, and pancreas. The effect of hydralazine on placental perfusion was opposite to the effect on the uterus (myometrium). Patients with the highest blood pressures tend to have the poorest placental perfusion. Intravenous hydralazine should be used cautiously in these patients. (Am J Obstet Gynecol 1987;156:356-9.)

Key words: Hydralazine, placental perfusion, hypertension

Pregnancy-induced hypertension is associated with increased vascular resistance and decreased uteroplacental blood flow,[1,2] which may in turn lead to perinatal morbidity and mortality. When drugs are used to treat hypertension in pregnancy, it thus becomes important to know the effect of the drug on placental perfusion. The effect of antihypertensive drugs on uteroplacental blood flow has remained controversial because of the lack of appropriate animal models of hypertension during pregnancy and the availability of suitable techniques to measure placental perfusion. The use of uterine artery flow probes to assess placental perfusion in the sheep model appears inappropriate as a drug may produce an increase in myometrial perfusion and a simultaneous decrease in placental perfusion.[3,4]

The genetically spontaneously hypertensive rat is regarded as a good model of human essential hypertension. However, during the latter part of pregnancy, the blood pressure decreases dramatically.[5,6] We have recently demonstrated that carbohydrate supplementation (10% sucrose in the drinking water) could prevent the normal fall in blood pressure during the last week of gestation, thereby producing a model of essential hypertension during pregnancy.[6] By the use of the radioactive labeled microsphere method to assess the distribution of cardiac output and perfusion of various organs, it is possible to distinguish between placental and myometrial perfusion.[4]

The number of drugs available to treat hypertensive disorders in pregnancy has greatly increased during the last few years. The model and technology now exist to test the effect of drugs on placental perfusion and to select drugs for human application on a more rational basis. This report describes the effect of hydralazine on placental perfusion in 16 spontaneously hypertensive rats during pregnancy.

Material and methods

Sixteen spontaneously hypertensive rats with timed pregnancies were obtained from Taconic Farms, Inc., Germantown, New York, and were housed individually in stainless steel wire-bottom cages. The temperature of the room was maintained at 22° C with the lights on from 6:00 AM to 6:00 PM. The animals were fed, as desired, a test diet (Teklad Mills, Madison, Wisconsin) providing the optimum daily amounts of macro- and micro-nutrients for the pregnant rats.[6] They were provided unlimited access to tap water, and from day 5 to day 21, they were given 10% sucrose in tap water to drink.

On day 21 of gestation, the animals were anesthetized with ether, and polyethylene catheters were inserted into the left ventricle of the heart via the right carotid artery and into the femoral artery as previously detailed.[4] The animals were then placed in a plastic restrainer cage and allowed to recover for 3 hours. The femoral arterial catheter was connected to a Statham P23Gb pressure transducer and arterial pressure was recorded on a Gould 2200S recorder. Cardiac output

Table I. Cardiovascular measurements before and after drug administration

Determination	*Before drug*	*After drug*	*Mean difference*	*p Value*
Mean blood pressure (mm Hg)	116.25 ± 2.95	80.31 ± 3.45	−35.94 ± 3.38	<0.001
Heart rate (bpm)	475.75 ± 5.41	491.20 ± 5.67	16.53 ± 6.99	0.033
Cardiac output (ml/min/100 gm)	36.16 ± 1.37	42.08 ± 2.01	5.93 ± 2.30	0.02
Total peripheral resistance (mm Hg/ml/min/100 gm)	197.02 ± 8.77	119.81 ± 9.20	−77.72 ± 10.88	<0.001

Values are means ± SEM.

and organ blood flow were then determined in the awake rats by the reference sample microsphere technique. A suspension of approximately 100,000 microspheres labeled with either gadolinium 153 or tin 113 (New England Nuclear, Boston, Massachusetts), 15 ± 3 μm in diameter, were sealed in a 15 cm segment of silicone rubber tubing. The microspheres were suspended in physiologic saline solution with Tween-80 (0.01%) added to prevent aggregation. The microsphere-containing catheter was wound around a wooden dowel rod to a height of 1.5 cm, placed in a gamma counting vial, and counted in a Model 1185 gamma well counter (Nuclear-Chicago, Des Plaines, Illinois) at the appropriate photopeak for the isotope used. After counting, the ends of the catheter were clipped and one end was attached to the left ventricular catheter while the other was attached to a syringe containing 0.5 ml of saline solution. The femoral reference blood sample collection was initiated at the rate of 0.5 ml/min, and after verification that it was withdrawing smoothly, the microspheres were flushed into the left ventricle with the 0.5 ml of saline solution during a period of 20 seconds. Collection of the arterial reference sample was continued for 1 minute after the end of the microsphere injection to ensure that all microspheres in transit in the arterial blood were collected. The arterial reference blood sample and syringe washings were transferred to a plastic gamma counting tube. The femoral catheter was flushed with saline solution and reattached to the pressure transducer, and heart rate and arterial blood pressure were recorded again.

The rats were then infused with hydralazine (25 μg/kg/min) via the left ventricle until mean arterial blood pressure decreased by 30 to 40 mm Hg (10 to 45 minutes). Upon completion of the infusion, the alternate set of microspheres was injected and a second arterial reference sample drawn. Each animal was then killed with an overdose of pentobarbital sodium. The entire length of ventricular catheter and silicone rubber tubing was wound around the dowel rod again to a height of 1.5 cm, inserted into the gamma counting tube, and recounted in the gamma well counter. The counts per minute for the calculation of cardiac output was determined as the difference between the counts per minute of the microsphere catheter before injection and the counts per minute of the entire catheter after injection.

After the rat was weighed, the uterus was removed and the fetuses and placentas were carefully detached from the uterine wall. The fetuses and placentas were separated from the amniotic fluid and membranes, gently blotted dry, and weighed separately; the placentas were placed in gamma counting tubes, three to four placentas per tube. The uterus was separated into right and left horns and placed in separate gamma counting tubes. The other organs and tissues were also placed in counting tubes to ensure that the levels of all tissues were kept below 1.5 cm to avoid loss of counting efficiency. The tissues and the arterial reference were counted in the gamma well counter, and the cardiac output and organ distribution of cardiac output were calculated as previously described.[4]

The statistical tests used were the Student t test for between-group comparisons and the paired t test to assess changes within the same groups.

Results

Total peripheral resistance decreased by 39%, resulting in a 36 mm Hg (31%) decrease in mean blood pressure (Table I). Heart rate increased by 4% and cardiac output increased by 16%.

Hydralazine significantly decreased vascular resistance to most organs with the exception of the placentas, stomach, and cecum, where it increased by 43%, 104%, and 44%, respectively (Table II).

Blood flow to the organs was redistributed and, although it increased to some, it was significantly reduced to the spleen (64%), stomach (55%), placentas (44%), cecum (41%), large intestine (39%), and pancreas (33%) (Table III). Hydralazine produced opposite effects on the uterus (myometrum) and placentas.

Rats with the higher blood pressures before drug administration had higher preplacental resistances ($r = 0.64$, $p = 0.004$) and tended to have lower placental blood flows ($r = -0.38$, $p = 0.07$). Resistance and placental perfusion after drug administration correlated significantly with the blood pressure before and after drug administration, and as the drug had a worsening effect on these parameters, the rats with the highest blood pressures before drug administration tended

Pre = Before drug administration; Post = after drug administration; BP = blood pressure.

to end up with the lowest placental perfusion after drug administration (Table IV).

Comment

Hydralazine lowers systemic blood pressure through relaxation of vascular smooth muscle. Reflex tachycardia and increased cardiac output occur in response to the decrease in peripheral vascular resistance. Of clinical importance is the differential distribution of cardiac output to the regional vascular beds after administration of hydralazine. Vascular resistance decreased and perfusion increased to organs such as the heart, lungs, kidneys, and liver. However, perfusion decreased to the spleen, pancreas, stomach, cecum, and large intestine. Although vascular resistance to the uterus decreased by 45%, preplacental resistance increased by 43% with a concomitant and highly significant decrease in placental perfusion.

Previous studies,[7, 8] with the use of a hypertensive sheep model with a flow probe on the uterine artery, described a 10% to 15% increase in uterine blood flow after administration of hydralazine. Lunell et al.[9] determined uteroplacental blood flow in 12 hypertensive women before and after the administration of hydralazine. To determine blood flow they injected indium In-99m and used a gamma camera connected to a computer. There was no significant change in uteroplacen-

tal blood flow or in uteroplacental vascular resistance. In both the sheep and human studies described above, placental perfusion could not be distinguished from myometrial blood flow. Unless myometrial and placental perfusion is independently measured, it is not possible to determine the effect of a drug on placental perfusion per se.

Our study confirms that vascular resistance and placental perfusion are correlated with the degree of hypertension (Table IV) and that, after administration of hydralazine, the lowest placental perfusion may occur in the women with the highest blood pressures. In patients with severe pregnancy-induced hypertension, those who received hydralazine had a significantly higher incidence of fetal distress than those who did not receive the drug.[10]

The spontaneously hypertensive rat has not previously been considered as an appropriate model for hypertension during pregnancy as the blood pressure falls progressively during the last week of gestation until it is in the normotensive range by term. The sympathetic nervous system of the spontaneously hypertensive rat (but not the WKY rat) is sensitive to carbohydrate intake.[6] Fasting suppresses sympathetic activity, resulting in a fall in blood pressure,[11] while carbohydrate overfeeding stimulates sympathetic nervous activity, thereby causing an increase in blood pressure.[12] These effects are thought to be mediated through control centers in the ventromedial hypothalamus.[13] We have recently shown that sympathetic nervous stimulation with dietary carboydrate supplementation maintains hypertension until parturition in the pregnant spontaneously hypertensive rat.[6] This appears to be a useful experimental model of essential hypertension in pregnancy in which to evaluate the effects of antihypertensive drugs on placental perfusion.

Fetal oxygen extraction: Comparison of the human and sheep

D. Rurak, D.Phil., P. Selke, M.D., M. Fisher, M.D., S. Taylor, A.H.T., and B. Wittmann, M.D.

Vancouver, British Columbia, Canada

To estimate fetal oxygen extraction in the human, the inverse, linear relationship between umbilical arterial Po_2 and oxygen extraction was calculated from measurements made on cord blood samples obtained after vaginal (n = 12) and cesarean (n = 16) delivery and used to predict oxygen extraction in utero. Comparisons with similar data from fetal lambs in utero and during labor and delivery indicate that extraction in the human and sheep fetus is 47% and 27%, respectively, at Pa_{O_2} = 20 mm Hg. For the human fetus to have extraction similar to that in the fetal lamb, vascular Po_2 would have to be substantially higher. This would lead to a higher umbilical venous oxygen content in the human, compensating for the lower umbilical blood flow and yielding a rate of oxygen delivery comparable with that observed in the fetal sheep. These data indicate that there may be significant quantitative differences in the fetal oxygen delivery systems in the human and sheep. (Am J Obstet Gynecol 1987;156:360-6.)

Key words: Fetal oxygen extraction, fetal Po_2, human fetus

Fetal oxygen extraction is the ratio between fetal oxygen consumption and oxygen delivery; it can also be calculated as the difference between umbilical venous (Cv_{O_2}) and arterial (Ca_{O_2}) blood oxygen$_2$ contents divided by umbilical venous oxygen content. In the fetal lamb, oxygen delivery is high, relative to oxygen consumption, and hence extraction is low, normally approximately 30%. When oxygen delivery falls, oxygen consumption can be maintained via an increase in oxygen extraction to approximately 60%.[1] Hence the high oxygen delivery and low extraction serve as an important reserve mechanism to compensate for reductions in fetal oxygen delivery. In the human fetus, umbilical blood flow is reported to be lower than in the fetal sheep, and it has been suggested that this is in part because of the higher hematocrit in the human fetus.[2, 3] However, fetal oxygen consumption appears to be similar in the two species.[4] This could require a higher level of oxygen extraction by the human fetus. Although determination of oxygen extraction in the human fetus in utero would be possible by using percutaneous blood sampling techniques, it is technically easier and ethically more acceptable to estimate oxygen extraction at delivery from measurements of oxygen content in paired cord arterial and venous blood samples.[5] In the present study, measurements of fetal oxygen extraction in the human fetus obtained in this manner are compared to values obtained from chronically instrumented fetal lambs in utero, after exteriorization by uterotomy and during vaginal delivery.

Material and methods

Human studies. Data from 28 human fetuses from 27 women were used in the study. Twelve fetuses were delivered vaginally and 16 by cesarean section. In the one twin pregnancy, twin A was delivered vaginally and twin B was delivered by cesarean section. Details of the pregnancies are given in Table I. In the patients undergoing elective cesarean section, the indications for cesarean section were a previous cesarean section in 10 cases, pregnancy-induced hypertension and intrauterine growth retardation in one case, and a previous infant affected by herpes in one case. The four emergency cesarean sections were performed for (1) delivery of a second breech twin, (2) uterine rupture after a trial of labor in a patient with a previous cesarean section, (3) chorioamnionitis and fetal distress, and (4) failure of labor to progress. All women undergoing cesarean section with epidural anesthesia received 10 L/min of oxygen by face mask, leading to an inspired oxygen concentration of ~40%. Only one infant with acidosis was delivered (pHa = 7.160), and this was in the vaginal delivery group. Postnatal outcome in all infants was normal.

At delivery, paried arterial venous blood samples (0.8 to 3.0 ml) were obtained from a double-clamped length of umbilical cord. The samples were collected in iced, heparinized syringes and stored capped in ice until blood gas analysis was performed, within 10 to 40 minutes of the time of collection.

Table I. Details of human pregnancies in which fetal oxygen extraction was measured

	Vaginal delivery	*Cesarean section*

Animal studies

Chronically catheterized fetuses in utero. Data from 27 chronically instrumented fetal lambs were used in the present study. The surgical and monitoring procedures have been described previously.[6] Briefly, operation was done at 115 to 130 days' gestation (term ~145 days) with the sheep under halothane anesthesia. Silicone rubber catheters were implanted in a fetal femoral artery, common umbilical vein, lateral tarsal vein, trachea, amniotic cavity, and, in some cases, a maternal femoral artery and jugular or femoral vein. Three groups of fetuses were studied.

NORMOXEMIC FETAL LAMBS (n = 10). These animals were used in a study of the effects of vasopressin on fetal oxygenation.[7] The blood gas data from the control period of these experiments are used as representative values from well-oxygenated fetal lambs.

HYPOXEMIC FETAL LAMBS (n = 12). Twelve fetuses were in this group. Six had arterial P_{O_2} values consistently <15 mm Hg for the entire duration of study, and six had Pa_{O_2} values >15 mm Hg; the mean P_{O_2} level for the entire group was 15.3 ± 0.6 mm Hg. In both groups fetal blood gases and oxygen consumption were measured before, during, and after a 60-minute period of 50% oxygen administration to the ewe. Some of the results from this study have been presented in abstract form.[8] In the present study, the data on Pa_{O_2} and oxygen extraction were used to examine the relationship between the two variables by means of regression analysis.

FETAL LAMBS DURING LABOR AND DELIVERY (n = 5). These animals were monitored continuously before and during spontaneous labor and vaginal delivery. The total monitoring time during labor ranged from 11 to 17.5 hours (mean = 13.9 ± 1.3). Measurements of blood gases, umbilical blood flow, and oxygen consumption were made every 2 hours until the last 2 to 3 hours of labor when the average sampling frequency was approximately 15 minutes. All of the fetuses were born alive, but one severely acidemic lamb died after several hours. Three sets of blood gas and oxygen extraction data from these preparations are presented in this report. Prelabor samples were collected the day before the onset of labor; early labor samples were obtained when increased uterine activity was first noted (13.9 ± 1.3 hours before delivery; and late labor samples were collected 4.2 ± 1.0 minutes before delivery, when the fetal head was in the vagina.

Exteriorized fetal lambs. Four exteriorized fetuses were studied at 130 to 140 days' gestation. They were used to compare umbilical blood flow estimates made with an electromagnetic flowmeter on the common umbilical artery with the steady-state antipyrine diffusion technique. These results were reported previously[6]; however, the blood gas data from these animals were not reported. The fetuses were delivered with the ewes under pentobarbital sodium anesthesia with care taken to minimize disturbance of the umbilical circulation and were kept adjacent to the ewe on a heated table. Observations were made for a period of 3 to 5 hours.

Measurement techniques. Blood gas values and pH were measured with an 11 micro 13 blood gas analyzer (Instrumentation Laboratory, Lexington, Massachussetts). The measurements were made at 39° C for the sheep samples and at 37° C for the human samples. Blood oxygen content was measured with a $LexO_2$ Con-K oxygen analyzer (Lexington Instruments, Waltham, Massachussetts). Fetal oxygen extraction was calculated as umbilical venous minus arterial oxygen content divided by umbilical venous content.

Differences in the measured variables among the various study groups were tested for statistical significance by use of the unpaired *t* test. Linear regression analysis, by the least-squares method, and significance tests for differences in slopes and y intercepts between different regression equations were done as described by Zar.[9] Values are presented as mean ± SE.

Results

Table II gives the mean values for umbilical arterial and venous blood gases and for fetal oxygen extraction for five groups of results: human fetuses delivered by cesarean section and vaginally, fetal lambs in utero, exteriorized fetal lambs, and fetal lambs during labor and delivery, with the latter group composed of prelabor, early labor, and late labor results. For the human

‡Equation: oxygen extraction = $a + b_1 (Pa_{O_2})$.

data, umbilical arterial and venous pH and base excess were significantly lower after vaginal delivery than after cesarean section, but there were no other differences between the two sets of human results. In both groups, there was a wide variation in vascular Po_2 and oxygen content; for Pa_{O_2}, the values ranged from 5.9 to 24.0 mm Hg for the vaginal delivery group and from 7.7 to 26.1 mm Hg for the cesarean section group. A similar wide range was observed for Ca_{O_2} and for umbilical venous oxygen levels.

For comparison with the sheep data, the human vaginal delivery and cesarean section results were pooled. Pa_{O_2}, pH, base excess, and umbilical arterial oxygen content in the human were lower compared with the values obtained from normoxemic fetal lambs in utero. Pco_2 and umbilical venous Po_2 and oxygen contents were not different between the human and antenatal sheep data, whereas hematocrit, the umbilical venous-arterial oxygen difference ($Cv_{O_2} - Ca_{O_2}$), and oxygen extraction were significantly higher in the human fetus. However, with exteriorization of the fetal lamb and during labor and delivery there was a deterioration in fetal blood gas status. With the exteriorized lambs, pH and base excess were significantly lower than with the fetuses in utero, whereas during labor there were progressive and significant falls in Pa_{O_2}, pH, base excess, Ca_{O_2}, and Cv_{O_2}. In both the exteriorized fetuses and the lambs at delivery, the umbilical venous-arterial oxygen difference and oxygen extraction were significantly greater than for the fetuses in utero but were not significantly different from the pooled human value.

Fig. 1 illustrates the relationship between Pa_{O_2} and fetal oxygen extraction in hypoxemic fetal lambs before, during, and after administration of a 50% oxygen mixture to the mother. There was a significant, linear relationship between these two variables ($r = 0.746$; $p < 0.001$). Similar plots are given in Figs. 2 and 3 for the human data and for the results obtained from fetal lambs in labor. For both sets of data, there was a significant relationship between Pa_{O_2} and oxygen extrac-

Base excess mEq/L	*Packed cell volume (%)*	*Oxygen content vol/100 ml*	*Venous-arterial oxygen difference vol/100 ml*	*Oxygen extraction (%)*

tion; r values for the human and sheep were 0.768 and 0.867. For the fetal lambs in labor there was also a significant relationship between arterial pH and oxygen extraction, and the marked variability in oxygen extraction at Pa_{O_2} between 8 and 16 mm Hg illustrated in Fig. 3 is in large part the result of variations in pHa (6.966 to 7.439) in the different fetuses at the end of labor.

Table III lists the regression coefficients and y intercept values for the regression equations calculated for the human and sheep data illustrated in Figs. 1 to 3. In the comparison of the pooled human results with the data from fetal lambs in utero, there was no significant difference in the respective regression coefficients, whereas the y-intercept value for the human (91.0) was significantly greater ($p < 0.001$) than the value in the sheep (57.3). For the fetal lambs in labor, the y-intercept value for $Po_2 = 0$, pH = 7.41 was 91.5, which was not different from the human value but was significantly higher than the value obtained from fetal lambs in utero. Moreover, the regression coefficient for Po_2 in the sheep labor group (−3.27 ± 0.49) was significantly higher than the coefficient from lambs in utero (−1.47 ± 0.18). The calculated regression equations for the three sets of data were used to predict fetal oxygen extraction at $Pa_{O_2} = 20$, pHa = 7.41. The calculated value for the pooled human data was 47.0%. This was significantly higher ($p < 0.001$) than the extractions of 27.3% and 25.8% calculated for the antenatal and intrapartum sheep data.

Comment

The results of this study indicate that oxygen extraction in the human fetus is substantially higher than in the fetal lamb, at least if vascular Po_2 is similar in the two species. The comparison between the two species was carried out by examining the relationship between umbilical arterial Po_2 and oxygen extraction and using the calculated regression equation to predict extraction in utero for $Po_2 = 20$ mm Hg. The linear, inverse relationship between the two variables does not indicate a direct causal relationship between the two variables. Rather it indicates that oxygen extraction and arterial Po_2 are altered in opposite directions by changes in either oxygen delivery or fetal oxygen consumption. For example, for a constant level of oxygen consumption, an increase in delivery would result in a fall in extraction and a rise in Po_2.[7] Conversely, a fall in delivery would lead to a rise in extraction and a decline in Po_2.[1] Similar reciprocal changes in the two variables would occur with alterations in fetal oxygen consumption when oxygen delivery is constant.[6, 10] Mathematically, an inverse, linear relationship between oxygen extraction and Po_2 is to be expected for the following reasons. First, as stated in the introduction,

$$\text{Oxygen extraction} = (Cv_{O_2} - Ca_{O_2})/Cv_{O_2}.$$

This can be rearranged to the form,

$$\text{Oxygen extraction} = 1 - Ca_{O_2}/Cv_{O_2}$$

Second, with both the human and the sheep data, Cv_{O_2} and Ca_{O_2} are significantly correlated. For example, with the human data, $Cv_{O_2} = 7.22 + 0.88\,Ca_{O_2}$ ($p < 0.001$). Substituting this into the equation for extraction yields

$$\text{Oxygen extraction} = \frac{1 - 0.017\,Ca_{O_2}}{1 - 0.12\,Ca_{O_2}}$$

This equation predicts an inverse relationship between the two variables, but it is not linear; instead, the negative slope decreases with increasing values of Ca_{O_2}. However, over the normal range of Ca_{O_2} ($\leq \sim 8$ vol/100 ml), the relationship closely approximates a

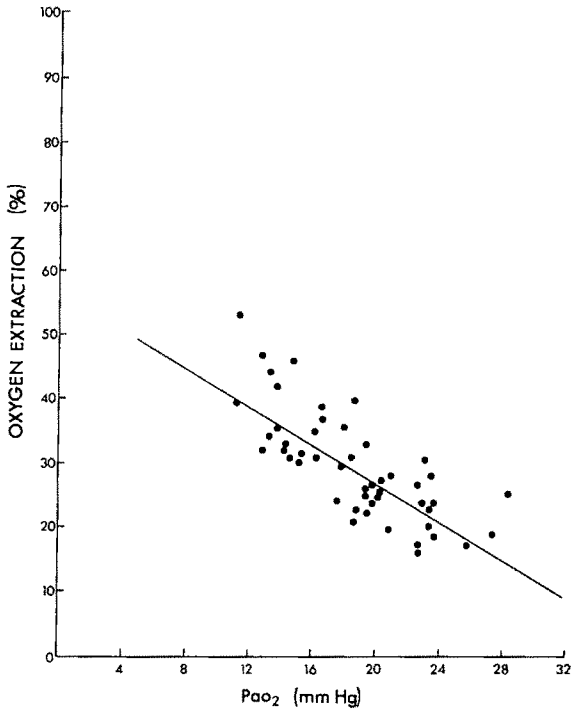

Fig. 1. Relationship between umbilical arterial P_{O_2} (Pa_{O_2}) and oxygen extraction in 13 fetal lambs before, during, and after administration of 50% oxygen to the mother. The line was fitted by regression analysis and conforms to the equation: oxygen extraction = 57.3 − 1.47 (Pa_{O_2}).

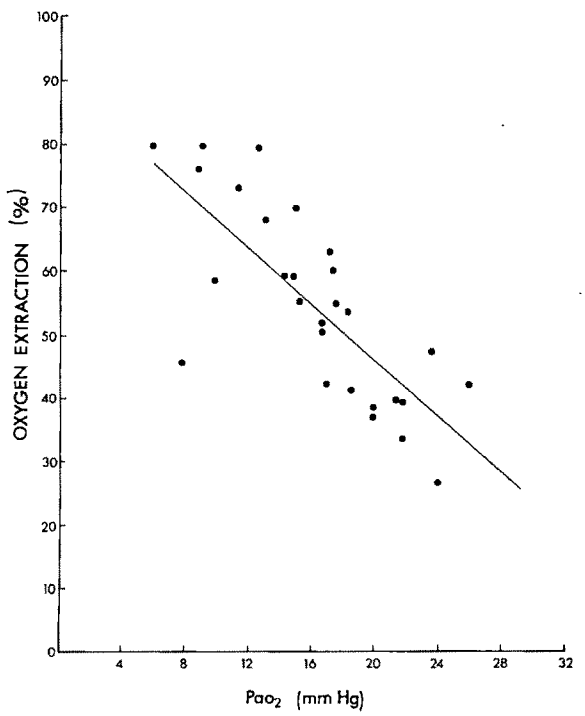

Fig. 2. Relationship between umbilical arterial P_{O_2} and oxygen extraction estimated in cord blood samples collected from 28 human fetuses after vaginal delivery (n = 12) or cesarean section (n = 16). The line was fitted by regression analysis and conforms to the equation: oxygen extraction = 91.0 − 2.24 (Pa_{O_2}).

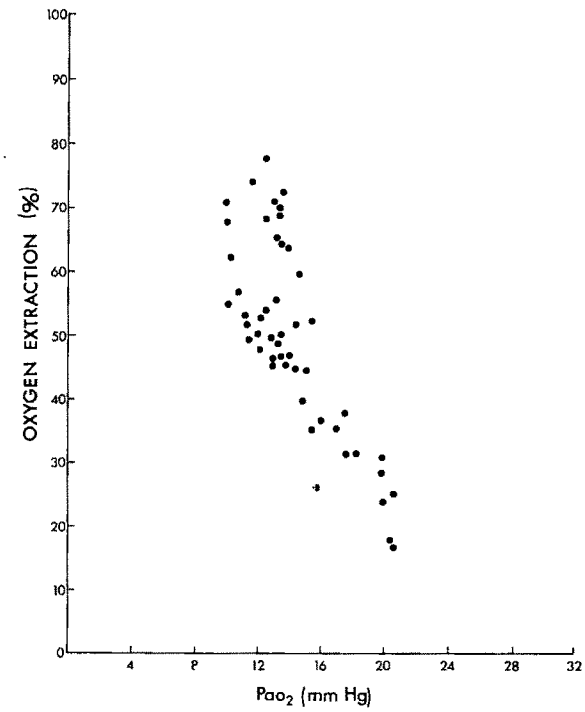

Fig. 3. Relationship between umbilical arterial P_{O_2} and oxygen extraction in five fetal lambs during labor and delivery. The relationship is best described by the equation: oxygen extraction = 91.5 − 3.27 (Pa_{O_2}) − 53.2(pHa).
